Most mechanical disturbances operate indiscriminately (i.e., they do not target specific organisms, as would selective herbivory, for example) and their impact depends on the ability of organisms to withstand the mechanical force. Thus, mechanical disturbances often winnow biological communities. For example, snow avalanches apply a bending stress on trees in their path that is a function of the snow’s density and the avalanche’s mass and drag. Susceptibility of woody species to breakage (vs bending) increases with tree size, leading to complex interactions between avalanche recurrence frequency and forest structure and composition in avalanche paths. Similarly, masses of attached barnacles and mussels in rocky intertidal environments become increasingly susceptible to detachment by waves as organism size and density increase. The same mechanical agent may create different kinds of disturbances depending on the size of the organism. In forests, for instance, woody stems may be most susceptible to breakage by wind when they are very small or very large, whereas intermediate-sized stems may be the most susceptible to uprooting by wind (Everham and Brokaw, 1996). When impacts of mechanical disturbances depend on the size or density of organisms, this produces feedbacks that influence population dynamics and create pronounced spatial patchiness at scales well below that of the disturbing process (Levin, 1992).

IV. PHYSICO-CHEMICAL DISTURBANCES

Physico-chemical disturbances, such as extreme cold, prolonged inundation of terrestrial organisms, hypoxic episodes in aquatic systems, freshets in coastal waters, and releases of toxic compounds (e.g., biological exotoxins such as those produced by the dinoflagellate *Pfiesteria piscicida*), reduce biomass by imposing lethal physiological stress. Physico-chemical disturbances do not involve mechanical force (except perhaps in the case of extreme cold when tissue damage is due to intracellular ice formation), and most physical and chemical disturbances leave dead tissues and organisms in situ. This contrasts with mechanical disturbances, in which space and resources are freed up through displacement of biological material. There are few studies comparing recovery processes under these two situations, but one might expect differences simply due to the presence or absence of residual detritus that could affect light, nutrient levels, and substrate quality (Reiners, 1983).

Like mechanical disturbances, physico-chemical disturbances have organism-specific impacts because of species-, age-, and size-specific physiological tolerances to environmental extremes. Thus, like mechanical disturbances, physico-chemical disturbances operate as an environmental filter of biological assemblages.

As mentioned previously, much of the emphasis in disturbance studies has been on sessile organisms such as plants and benthic invertebrates. Some large-scale physico-chemical disturbances may be somewhat distinctive in that they can kill large numbers of highly mobile organisms. For example, episodes of anoxia can
cause massive fish kills in estuaries and lakes. Severe cold weather can selectively kill large numbers of birds. In these instances, the suddenness and magnitude of the events prevent animals from escaping, a phenomenon which can also be observed during extreme wildfires.

Fire is obviously a special case of a physico-chemical disturbance because biomass is both transformed and removed in the combustion process. Fire is also unquestionably one of the most pervasive and obvious disturbances in terrestrial ecosystems, and an enormous scientific literature has been devoted to the subject of fire events and fire regimes. It is discussed here to illustrate in more detail the concepts of disturbance mechanisms and disturbance regimes.

The occurrence of fire requires an ignition, fuel combustion, and spread, each of which in turn depends on many physical and biological factors, notably climate, weather, fuel structure and chemistry, and topography. The most important effects of fire are partial or complete combustion of aboveground vegetation, mineralization and deposition of plant tissues as ash and charcoal, extreme heating of the local atmosphere and topsoil, and killing of selected plants, seeds, spores, and animals both above- and belowground.

Figure 1 presents a simple conceptualization of factors that influence fire dynamics at three distinctive spatial and temporal scales in Mediterranean-climate shrublands. The fire fundamentals triangle (Fig. 1a) captures essential elements of the actual combustion process, which occurs at minute scales and depends on oxygen, heat, and fuel. The timing, size, and severity of a wildfire (or controlled fire) event, which may last hours to weeks and extend over hectares to thousands of square kilometers, depends on local weather, topography, and fuel bed. Finally, the fire regime of a landscape depends on complex interactions among climate, vegetation, and ignition factors operating over decades to centuries.

Fire creates strong biological patterns over a broad range of spatial scales. At the scale of individual plants, biomass combustion, soil heating, and nutrient removal can vary widely, imposing very fine-grained variation in mortality and postfire conditions that is manifested in equally fine-grained patterns of biological recovery. A coarser pattern can be created at the scale of entire populations (vegetation stands). Fire severity and vegetation removal can vary with topography, soil, vegetation, and wind conditions, and distance from source populations for seeds and animal colonists can influence community recovery. At still broader scales, landscapes are composed of fire mosaics, a patchwork of stands with differing fire histories and biotic communities. This landscape mosaic is one of the factors aiding in the long-term persistence of species with different fire tolerances. The spatial patterns from individual plant distributions to landscape mosaics all affect

![Figure 1](image_url)

**FIGURE 1** Hierarchical model of fire controls at successively coarser scales of space and time. Connections between fire and individual controls indicate potential feedback loops (after Moritz, 1999, with permission).
the location and severity of future fires and their ecological impacts.

Fires are obvious, discrete events, and research on wildfire history has provided many useful models and methods for characterizing temporal and spatial properties of disturbance regimes (Johnson and Gutsell, 1994). Temporal properties such as time-since-fire (survivorship) and fire interval (mortality) are described using probability distribution functions, notably the Weibull and negative exponential distributions. Fire mosaics and their dynamics have been described using spatial Markov chain models, percolation theory, and spatial autocorrelation statistics. These quantitative characterizations are useful for describing changes in fire regime over time, for comparing different areas, and for estimating wildfire risk.

V. DISTURBANCE BY HERBIVORES AND PREDATORS

In many ways, consumers (and pathogens) have the same effects as other agents of disturbance in that biomass is removed and new opportunities for recruitment are created. There are some distinctive features, however, of disturbances by herbivores and carnivores. Most obviously, they operate at the relatively fine scale of individual consumers, and they leave a very different biological legacy than mechanical and physico-chemical disturbances because biomass is concentrated and converted into heat, new tissues, and discrete waste products. The waste products are frequently deposited away from the disturbed area. For example, frass from defoliating caterpillars in tree canopies falls to the soil surface. Shade-seeking ungulates in African savannas deposit a disproportionate amount of urine and feces under trees. Elk migrations lead to a net transport of nitrogen from summer ranges to winter ranges.

Foraging is also a far more selective form of disturbance than other disturbance mechanisms. Organisms (including humans) preferentially occupy specific sites and microsites and focus on specific plant resources, creating patchiness at many scales. Most plants are unpalatable to most herbivores, and selective herbivory by dominant grazers can exert strong, directional effects on community composition, structure, and ecosystem processes. These effects may be amplified by strong feedbacks between consumption, food quantity, and food quality. For example, moose in boreal ecosystems selectively browse nitrogen-rich deciduous species and avoid coniferous species. Over time this promotes nitrogen sequestration in conifer litter and accelerates succession of deciduous to coniferous plant communities (Hobbs, 1996). Disease spread from infected to susceptible hosts and the development of resistance in infected individuals is somewhat analogous in terms of the strong spatio-temporal feedbacks between the disturbance process and the state of the system.

Many consumers act as mechanical, chemical, and biological agents of disturbance. Perhaps the most sensational example is that of beavers, which selectively fell trees, dam streams, and inundate floodplains. Similarly, burrowing animals such as pocket gophers can operate as "physical ecosystem engineers" creating pervasive changes in the abiotic and biotic environment by redistributing soil and nutrients, altering soil hydrology and canopy light regimes, and altering vegetation composition and dynamics.

VI. INTERACTIONS AMONG DISTURBANCE MECHANISMS

Disturbances can interact in complex, nonlinear ways across space and time. One disturbance may promote another, such as occurs when dry-season fire in Mediterranean-climate shrublands promotes flooding and debris flows during the ensuing wet season. Conversely, one disturbance mechanism may reduce the likelihood of another. For example, grazing reduces the likelihood of fires in grasslands and the likelihood of crown fires in some forest ecosystems. Nearshore communities that are heavily impacted by wave disturbance may also experience lowered rates of predation. It is not difficult to imagine many such interactions operating across a wide range of spatial and temporal scales.

Disturbances often play an important role in invasion and spread of exotic species. In Hawaii, for instance, invasion of the nitrogen-fixing shrub, Myrica faya, was facilitated when native vegetation was thinned by heavy ash deposition from a volcanic eruption. There is a growing list of examples in which disturbance promotes the spread of an invasive species and then that species initiates ecosystem changes that introduce new disturbance processes. For example, in the western United States cattle grazing in shrub steppe promoted the spread of the exotic grass, Bromus tectorum, and the presence of a dry grass layer then increased wildfire size and frequency in that system, in which fires were historically uncommon.

As mentioned in Section 1, compounded disturbances, or disturbances of communities already stressed
by abiotic or biotic forces, can have large and persistent effects on ecological communities if they occur in such rapid succession that they disrupt normal recovery processes. Repeated burning over a series of 2 or more years is a common means of converting shrublands to grasslands in semi-arid ecosystems. In a particularly dramatic example, Hughes (1994) describes the decline of corals in Jamaica due to the combined effects of overfishing, two major hurricanes, and disease that caused mass mortality in sea urchins. These impacts appear to have collectively precipitated a massive phase shift from coral-dominated to algal-dominated reefs.

VII. HUMANS AS AGENTS OF DISTURBANCE

For many millennia humans have been manipulating ecosystem processes with varying impacts on ecosystem function and species distribution. Human activities that create disturbances at spatiotemporal scales to which organisms are adapted generally do not affect long-term changes in community composition or structure. For example, shifting agriculture in the humid tropical forests, like hurricanes, creates small, temporary forest clearings and results in landscape mosaics within which most species can persist. In contrast, commercial forest cutting and cropland and pasture development are large and/or persistent disturbances that can produce regional extinction of species and require much longer periods for forest recovery (Attiwill, 1994).

Another widespread human impact has been to regulate or arrest disturbances such as fires, floods, or animal activities that create habitats on which some species depend. Even when human ecosystem manipulations are, by design, modeled after a particular disturbance, it is difficult to incorporate all disturbance-related changes in the environment. For example, forest harvesting can occur at the spatiotemporal scale of a natural fire regime, but the post-fire nutrient pulse and legacy of dead snags are no longer factors in the recovering ecosystem. Streams may be regulated to mimic periodic flooding, but dams often inhibit fish migrations that would happen at that time (and agencies will understandably stop short of re-initiating very high-magnitude flood events).

As humans fragment terrestrial habitats through land-use conversion and aquatic systems through impoundments, diversions, dredging, trawling, and construction, permanent fragmentation of habitats is superposed on dynamic disturbance mosaics, causing changes in disturbance regimes. Such fragmentation can retard disturbance spread (e.g., the spread of fire or disease), alter disturbance regimes in remnant patches, and create edge environments with novel disturbance regimes. Local human activities can have large cumulative effects. For example, the building of roads alters the natural cycles of erosion and landslide initiation, whereas agricultural land use often leads to the concentrated nutrient inputs and changes storm flows in receiving water bodies. In fact, most human activities have the capacity for altering historical disturbance regimes in some way.

At the broadest scale, humans are changing global climate patterns, and nearly all mechanisms of disturbance and disturbance effects are ultimately tied to climate processes. Changes in disturbance regimes during global climate change are inextricably tied to other ecological responses to changing climate, affecting whether species can persist in their current ranges or can invade new areas of more suitable environmental conditions. The tight coupling between biotic processes and structures and most disturbance patterns and processes—a recurrent theme in this article—creates complex feedbacks that could amplify or moderate the effects of global climate change on disturbance regimes, species, and ecosystems.

DIVERSITY, COMMUNITY/REGIONAL LEVEL

Howard V. Cornell
University of Delaware

GLOSSARY

between-habitat diversity Degree of dissimilarity in species composition between two habitats. The greater the number of species shared by two habitats, the lower the between-habitat diversity.

metacommunity An assemblage of species in a patchy landscape, each species comprising a metapopulation in that its distribution shifts among habitat patches because the distribution is determined by colonization and extinction dynamics.

metapopulation Group of subpopulations distributed among habitat patches in a landscape, each subpopulation being subject to periodic extinction and subsequent recolonization from other occupied patches.

richness Simplest measure of diversity, represented by a count of the number of species in some ecologically meaningful unit (community, metacommunity, region) without regard to variation in the number of individuals per species.

saturation Upper limit to species richness within a community, set by species interactions, and independent of the pool of colonists to which that community is accessible.

species pool Set of species that are able to colonize a habitat of interest.

type I community An assemblage of species where the richness is a constant proportion of the number of species occurring in a larger geographic unit in which the community is embedded.

type II community An assemblage of species where the richness is independent of the number of species in a larger geographic unit in which the community is embedded.

AN ECOLOGICAL COMMUNITY IS A COLLECTION OF SPECIES LIVING CONTEMPORANEously IN THE SAME PLACE and comprising populations of individuals that are spatially interspersed and among which direct and indirect interactions can potentially take place. Communities are nested within larger biogeographical regions that comprise many different habitats and that have unique evolutionary histories. Species can disperse among suitable habitats in the region and thus define the species pool for communities occupying those habitats. Species interactions, habitat differences, history, and dispersal have all been hypothesized to influence species diversity in communities, and thus community and regional species diversity are inextricably linked. This article presents two perspectives on
the control of community and regional diversity, the nature of the linkage between community and regional diversity, and methods for examining this linkage. Guidelines for synthesizing community and regional perspectives are also considered.

I. TWO PERSPECTIVES ON THE CONTROL OF COMMUNITY/REGIONAL DIVERSITY

A. Local Control of Species Richness

1. The Volterra–Gause Perspective

One of the most obvious and fundamental facts of ecology is that all species do not occur everywhere. Instead, each species has a unique distribution determined by its ecological context and evolutionary history. Nevertheless, species distributions overlap to varying degrees so that some places support more species than others do. Such variations in species richness have been a central issue in ecological and biogeographical studies at least since the turn of the century. Until recently, explanations focused mainly on processes operating within ecological communities over relatively short periods of time. This perspective arose out of a desire to add scientific rigor to ecological studies by focusing on mechanisms and ignoring history. A mechanistic approach made it possible to model ecological systems with simple equations and to test these models and their assumptions with carefully collected data.

One of the earliest truly influential models in community ecology was developed by Vito Volterra (and independently by Alfred Lotka) in the mid-1920’s. This model is a set of simple differential equations describing competition between two species in terms of reductions in per capita population growth rates by interactions among individuals. When the model is analyzed at equilibrium, the outcome of competition (coexistence or competitive exclusion) is easily predicted from the intensity of interactions within species relative to those among species. If populations limit their own growth more than the growth of other populations, the two species will coexist. If they limit other populations more than themselves, one will exclude the other. The model and its assumptions were later tested by G. F. Gause in laboratory systems comprising several species of protozoa. The tests lent strong support to the model, and as a result the so-called Volterra–Gause perspective has become a metaphor for the way in which ecologists think about control of species richness.

According to this perspective, species richness in a biogeographical region may indeed be determined in part by history. However, history has little relevance to the upper limits on local richness within communities. Instead local richness is limited primarily by species interactions (predation, parasitism, herbivory, competition, mutualism) in conjunction with abiotic conditions (water, nutrient, and energy availability, chemistry, temperature, disturbance). In other words, the outcome of interactions is determined in large part by the abiotic conditions in which they occur. For example, lower concentrations of a particular nutrient or lower water availability might favor one plant species in competition with another, but higher values of these factors might result in a reversal of competitive dominance. The number of species in the biogeographical region provides a species pool from which the local communities are drawn, and all species have the potential for colonizing all habitats in the region. Since habitats vary in their abiotic conditions and resident assemblages, only those species capable of coexisting in a given milieu will establish successfully. Differences in species richness thus result from differences in the abiotic template and species composition among habitats. In a recent series of publications from the early 1990s, James Drake has shown that the colonization order of species into a habitat can also have some effect, and communities can exhibit multiple stable points representing different levels of species richness.

A crucial element of this perspective that derives directly from the Volterra model is that communities exist at a dynamic equilibrium. For example, in the case of competition, population levels of the resident species are limited by resource availability and physical conditions. Thus, if sufficient time elapses and there are no perturbing disturbances to the community, the number of species will saturate at a level determined by the number of limiting resources and physical factors. At saturation, species are sufficiently similar in their resource use that finer subdivision of resources becomes increasingly difficult and new colonizations into the community must be accompanied by extinctions of current residents. If habitats throughout the region are all identical and saturated with species, then the total number of species in the region is limited to the total number coexisting within each identical habitat. That is, community and regional richness are identical and regional richness is limited by the same factors that limit local richness.

Since all habitats are not identical, species within the region have the option of partitioning habitats as well as resources and thus the same set of species will
not occur everywhere in the region. Nevertheless, local processes are still limiting both local and regional richness, but limits on regional richness now result from interplay between species interactions and spatial habitat variation. The greater the number of habitats, the greater the between-habitat diversity and the greater the number of species in the region relative to those within a single community. Historical processes such as massive extinctions might reduce the number of species in the region for a time, and subsequent evolution, speciation, and dispersal might generate a new biota that differs from the previous one. However, the essential feature of this viewpoint is that given sufficient time, the imprint of history on species richness will fade, communities will fill up and become saturated, and processes operating locally will also limit richness regionally.

Even strict adherence to the Volterra–Gause viewpoint still allows for other factors to affect local and regional richness. All else being equal, larger localities and regions will support more species than smaller ones as predicted by the species–area relationship. In addition, some species within a region might be ecologically equivalent and thus might be able to substitute for one another within a given community type. Chance might determine what species occupies what particular community, in which case ecologically equivalent species could increase regional richness without affecting local richness. Finally, spatial interspersion of habitat types might allow species adapted to one habitat type to persist in an adjacent, less favorable habitat type by means of propagule flow. This so-called source–sink effect proposed by Ron Pulliam in 1988 would increase local richness in the less favorable habitat above that which would be self-maintaining in the absence of immigration. Although these factors may have important impacts on species richness, they do not alter the premise that the primary direction of control on species richness is from the local to the regional level.

An ecological community at equilibrium and not subject to vagaries of history evokes a powerful image that continues to influence modern ideas about species diversity. Robert MacArthur’s (1972) book represents the pinnacle of this viewpoint, although he recognized that the equilibrium assumption and local control of richness did not apply to all communities. There are clear recent demonstrations that species interactions have strong influences on community structure and might exclude species from the community (see Lawton, 1999, for a brief review). In short, the Volterra–Gause perspective has been a useful guide to a limited understanding of the mechanisms by which particular communities are structured. However, this understanding has led to few if any general patterns or rules that apply to most systems (Lawton, 1999).

2. Species–Energy Theory

Another view of local control of species richness comes from the ecosystem perspective, and has been termed “species–energy theory.” The theory was developed mainly by David Wright, David Currie, and Brian Maurer (1993). Species–energy theory posits that local and, ultimately, regional richness are limited by available energy within the local environment. Available energy limits local richness by placing ceilings on the population densities of individual species. As energy decreases, densities decrease, random extinctions increase, and local richness is reduced. Available energy can be scaled up to whole regions by multiplying the energy per unit area by the total area of the region. Thus, population densities and species richness over the whole region are also controlled by energy availability.

Although the theory in this simplified version posits local control of local and regional richness, it differs from the Volterra–Gause viewpoint in that species interactions are of secondary importance in limiting richness. Energy can have direct and independent effects on population levels to increase richness rather than mediating interactions among species. Interactions can be included in the model, but they are not necessary for limits on richness to occur. Species–energy theory is very similar to island biogeography theory, which proposes that species richness is a balance between colonization and extinction rates in a local habitat. Smaller habitats have higher per species extinction rates and thus lower species richness as predicted by the species–area relationship. The main difference between the two theories is that species–energy theory substitutes energy availability for area as the predictor of species richness.

A recent literature review by David Wright and others demonstrated that several proxy variables for energy availability (precipitation, potential or actual evapotranspiration, productivity) are indeed strong predictors of species richness for various taxonomic groups (Table 1). However, it is not clear whether energy is the direct cause of richness variation, or whether it simply covaries with other possible causes such as area effects, habitat heterogeneity, species interactions, and historical effects. It is also not clear whether the assumptions of the theory are always met in particular studies. For example, it is assumed that energy limitation should operate at the local scale where individuals of each species seek sufficient energy to persist in the commu-

Note: Factors investigated as the principle determinant of species richness in 82 correlations from 53 studies.

*Numbers in parentheses indicate the number of correlations that were omitted from further analysis because no correlation coefficient was reported.

However, it is at the scale of the local community that the correlation between energy and richness is weakest and most variable; the correlation is strongest at larger spatial scales (104–108 km²). It is also assumed that average population size and species richness should increase together with available energy, but this is not always the case. In particular, David Tilman and Pacala have pointed out that plant systems often show an inverse relationship between per species population sizes and energy as predicted by the −3/2 power law, yet species richness commonly increases with energy in the expected way. Despite these limitations, energy can be a useful variable for estimating richness at larger scales because covariation is high regardless of the underlying causes, and because energy data (or proxies) are available for most geographic areas.

At more local scales, species interactions among resident populations may come into play, altering any potential increases in richness with energy availability. Such interactions might partially explain the more variable relationship between energy and richness within communities. Increased energy can lead to increased biomass of the total community, which in turn can lead to increases or decreases in average population density depending on the intensity of interindividual interactions and the size plasticity of the taxa involved. But it is the changes in the relative allocation of energy among species that are critical for predicting changes in richness. If allocation changes as energy availability increases, for example, caused by shifts in competitive superiority or ability to avoid predation, then the population densities of some species may increase while other species may be driven extinct. Richness can thus increase or decrease with increased energy depending on the circumstances. It is at this point that the species-energy theory converges with the Volterra-Gause viewpoint since the environment is now mediating interactions among species.

3. The Diversity–Productivity Relationship

The idea that richness can change with energy availability in unpredictable ways has had a long history under the guise of the diversity–productivity relationship. Productivity is a measure of energy availability to the
community and has been shown to affect local richness in contradictory ways; richness either increases, decreases, or shows no relationship with productivity depending on the assemblage. Recently it has been suggested that these contradictory relationships may just be incomplete segments of an overall hump-shaped, unimodal relationship over a broader range of productivity. In other words, richness peaks at intermediate productivity levels and declines toward the extremes. Different taxa can show richness peaks at different levels of productivity, resulting in unimodal curves that are displaced along the productivity spectrum. No ecological pattern is universal and, accordingly, contradictory relationships between richness and productivity need not always imply a truncated hump. Indeed, evidence for this possibility is currently limited at best (Watson et al., 1999). Monoecious relationships may be just as frequent as unimodal ones. Nevertheless, the unimodal curve is a useful synthetic construct and it is sufficiently frequent to invite explanation. Moreover, the same explanations for each arm of the hump may apply equally well to monotonically increasing or decreasing relationships over a particular range of productivity.

It is not clear why richness shows this strange relationship with productivity, and the pattern remains one of the most important unresolved mysteries in community ecology. The hypothesis that productivity differences are directly responsible for the unimodal relationship assumes that productivity is uniformly distributed among sites. In other words, low-, medium-, and high-productivity environments occur with equal frequency. If medium-productivity sites are more frequent than low- or high-productivity sites, then the unimodal curve might just be a reflection of simple species-area effects. There is some evidence to suggest that this is not the case (Rosenzweig, 1995), but the possibility has not been extensively tested. At the very least, diversity-productivity correlations should be corrected for unequal area effects before a causative link between these variables is seriously considered.

Unimodal curves (as well as monotonically increasing or decreasing ones) can occur at different spatial scales (local, landscape, regional, continental), but their frequency changes as spatial scale increases. Monotonically increasing patterns are more common at larger scales and unimodal patterns are more common at local scales (Fig. 1). Moreover, the mechanisms responsible for patterns at each scale probably differ (Watson et al., 1999). Since the within-community, among-community, and local scales are where ecological processes become important, theories that consider changes in species interactions and local environmental conditions along productivity gradients are the most relevant.

The decline to the left of the hump may derive from increased environmental stress or the direct effects of energy reduction on population levels as proposed by species-energy theory. Other mechanisms, such as increases in disturbance rate, poor recovery from disturbance due to slower population growth rates, declines in territoriality, and environmental heterogeneity have also been suggested to play a role. The decline to the right of the hump may involve some form of interaction mediation among species, such as increased intensity of competition and predation or increased population dynamic instability within food webs at high productivities. Such declines would then provide strong support for the idea that species interactions limit species richness in accordance with the Volterra-Gause viewpoint. However, it is important to point out that richness declines in highly productive areas may also result from regional effects. For example, if productive habitats are relatively rare, they are likely to be surrounded by larger, less productive areas and thus isolated from a large source pool of species adapted to productive conditions. As previously mentioned, area effects may also contribute to low richness. Regional effects must therefore always be taken into consideration when analyzing diversity-productivity relationships.

Tests that distinguish among these various theories are difficult to perform and have thus far been limited. Comparative approaches, although they require less disruption of the community, might not be able to distinguish among alternative theories unless natural "experiments" in which selected mechanisms are not operating can be found. Experimentation has better control of confounding variables, but care must be taken to provide enough time for all processes that contribute to changes in richness to ensure that they are allowed to respond to the manipulation. For example, in a 1999 review, Laura Gough and co-workers found that fertilization experiments consistently resulted in increases in inorganic nutrient concentrations, which in turn intensified species interactions in herbaceous plant communities. Fertilization increased productivity and reduced species richness across a broad range of community type, due primarily to increased dominance by one or a few species. These experiments certainly demonstrate the potential of interaction mediation to limit community richness. However, the relevance of such studies to richness declines in natural communities at highly productive sites is questionable. Fertilization reduces diversity even at poorly productive sites, where theory predicts that diversity should increase.
FIGURE 1 Breakdown of published plant and animal studies showing a unimodal, positive, negative, or no relationship between species diversity and productivity at four spatial scales. The number of studies in each histogram (n) is shown. (From R. B. Walde, M. R. Willig, C. F. Steiner, G. G. Mittelbach, L. Gough, S. I. Dodson, G. P. Juday, and R. Parmeter (1999). The relationship between productivity and species richness. Annu. Rev. Ecol. Systematics, 30, 257-300, with permission.)
This anomalous result may be a consequence of the short-term nature and small spatial scale of such experiments. Species adapted to the higher productivities of the fertilized sites might not be able to reach them if they are isolated in space or time. More appropriate experiments should therefore manipulate the species pool to simultaneously test for the effects of productivity and the dispersal effects on richness. If pool limitation is the cause of the anomalous results, then experimentally boosted recruitment to low-productivity sites by an appropriate species pool should generate higher species richness with higher fertilization rates. Naturally, the species selected for the boosted recruitment should be well-adapted to the increased nutrient levels at the fertilized sites. High-productivity sites, on the other hand, should remain depressed in diversity owing to interspecific interactions. Some combination of comparative and experimental approaches will probably be required to solve the mystery of the diversity-productivity relationship. Regardless of the methods used, it is important that it be solved, since it represents one of the clearest possibilities that local richness is locally controlled. It also provides a single framework that subsumes both species-energy theory and Volterra-Gause processes.

4. Theory Doesn't Always Predict

Local Control

Without question, the Volterra-Gause viewpoint has stimulated much research on the factors that control species richness. Nevertheless, the fundamental premise that local processes control local and ultimately regional richness may be incorrect for many systems. Even the restrictive Volterra-Gause models do not always predict limits on species richness due to local mechanisms. After appropriate modification to incorporate some realistic features of environments and species, such as spatial heterogeneity, environmental fluctuations, nonlinear population growth responses to environmental change, and trade-offs among species in their ability to compete in different environments, the models often predict that there are no upper limits on local richness (Tilman and Pacala, in Ricklefs and Schluter, 1993). Moreover, the Volterra-Gause assumption that population levels are at equilibrium, may not commonly be met in natural communities. In a classic example, periodic disturbance can drive populations below equilibrium, where the outcomes of interspecific interactions are never fully realized. More species can thus invade than would be allowed by equilibrium population levels.

If real communities have any of these features, it is not likely that local richness will reach saturation as predicted by the simplest models. Evidence from real communities suggests that lack of saturation is indeed common. Lack of saturation raises the possibility that factors external to the community may ultimately determine local richness. As a consequence, the factors that determine regional richness must also be sought elsewhere. In the Volterra-Gause view, regional richness is limited by a combination of the number of species within saturated habitats and the number of habitats within the region. If communities within habitats are not saturated, control on regional richness cannot be exerted at the within-habitat scale. Moreover, the number of habitats within a region is not fixed and may be more an effect of the number and kinds of species in the region than a cause of richness limitation at the between-habitat scale (Rosenzweig, 1995). In other words, the more species there are in the region, the more finely habitats can be partitioned and the more distinct habitat types that can be identified. How, then, do differences in richness among regions arise? And what relevance do these differences have for local richness? An alternative to the Volterra-Gause viewpoint that addresses these questions is thus needed.

B. Regional Control of Richness

1. Regional Processes

The alternative view rests on an idea that actually predates the Volterra-Gause view, namely, that regional richness is set to a large degree by historical biogeographical factors. The importance of history is implicit in the traditional definition of a biogeographical region that relies in part on the presence of a distinctive native biota. The presence of large groups of indigenous species implies that the region has undergone a period of isolation and independent evolution. Thus, the numbers and kinds of species that occur across the region are determined to some degree by its unique historical development. These different histories might result in widely divergent species richnesses among some components of the biota, which in turn may be reflected in local communities. Under this scenario, local richness is not limited by species interactions as predicted by simple Volterra-Gause models, but becomes some function of the number of species in the region that are able to colonize and persist in a given habitat. The richness of the community embedded within the region thus retains some of the region's historical signature.

The key prediction arising out of this scenario that distinguishes it from the Volterra-Gause model is that localities in richer regions can support more species
FIGURE 2  Phylogenetic and biogeographical patterns that suggest association by descent. Species sets (2, 7, 12) and (3, 6, 13) comprise communities that were found on opposite sides of a geographic barrier. The phylogeny (A) indicates that species sets (2, 3, 7, 8), and (12, 13) each had a common ancestor. These two patterns suggest that both communities descended from a common ancestral community that existed before the barrier was formed. (B) The species in each extant community are thus associated because their ancestors were associated. (From Brooks and McLennan, in Ricklefs and Schluter. (1993). Copyright © 1993 by University of Chicago Press.)

than those in poorer ones even though the localities are environmentally similar. This is simply because species co-occurrences within localities are determined to some extent by the same factors that determine regional co-occurrence. In their 1991 book *Phylogeny, Ecology, and Behavior*, Brooks and McLennan pointed out that regional co-occurrence can come about via two processes: association by descent and association by colonization. In association by descent, two species co-occur because their ancestors co-occurred. In other words, the community was assembled from ancestors in the distant past, and the species present today evolved *in situ* from members of the ancestral community, most likely by geographic isolation (Fig. 2). The community is thus rich or poor because the region in which it is embedded was historically rich or poor. In association by colonization, two species can co-occur because one evolved elsewhere and migrated into the region. Communities are open to colonization because (1) interactions are not limiting richness, (2) the colonizing species uses niche space that is not occupied by the *in situ* residents, or (3) after contact with the residents, evolution of niche partitioning occurs. In association by colonization, the community is rich or poor because its region has high or low barriers to colonization from elsewhere. It is likely that real communities are mixtures of colonists and *in situ* descendants, and Brooks and McLennan have pioneered the development of phylogenetic methods to distinguish between these two groups.

The influence of higher colonization rates into a region on regional and thus local richness is obvious, but the role of history is less so. Why are some regions historically richer than others? The answer to this question must involve region-specific differences in historical speciation rates, extinction rates, or both. Some processes might also act to increase the speciation rate relative to the extinction rate. For example, some taxa may have developed key innovations that allowed them to enter a new adaptive zone and undergo an adaptive radiation. The region may have been simultaneously dissected by colonization barriers, disrupting gene flow
among many populations and resulting in a burst of speciation.

Latham and Ricklefs present a possible example in the evolution of frost tolerance and proliferation into the temperate zone by forest trees. Asian temperate forests have three times more tree species than North American forests and six times more than European forests. Because Asia may be particularly diverse topographically and has no geographic barrier between the tropical and temperate zones, such proliferation may have occurred more frequently than in North America and Europe, where such barriers do exist (Ricklefs and Schluter, 1993). Alternatively, some taxa may undergo non-adaptive bursts of speciation resulting from inherent biological attributes, including genetic peculiarities (e.g., chromosomal anomalies or polyploidy), mate recognition and selection, or other factors. A dramatic example is the anomalous diversity of the Hawaiian Drosophila. The proliferation of this genus in Hawaii far exceeds that in any other region of equivalent area and has been attributed to a strong tendency for sexual selection in the Hawaiian taxa (see Cornell and Lawton, 1992). Adaptive and nonadaptive radiations might be distinguishable by differences in the relationship between speciation rate and richness. In adaptive radiation, speciation rate should at first exceed extinction rates and then come into balance with extinction as regional richness increases and the adaptive zone fills up. Nonadaptive radiations do not require ecological diversification, and thus speciation and extinction rates should be unaffected by regional richness. Adaptive and nonadaptive radiations are not mutually exclusive and both could be operating in the same clade.

Other processes might act to increase extinction rates relative to speciation rates in some regions. Increased probability of extinction is believed to be linked to low average population size, which in turn is correlated with geographic distribution. Thus, any event that reduces a species' range, such as habitat destruction or displacement by an invader, is likely to decrease its time to extinction. Returning to temperate forest trees, glaciation in conjunction with mountain barriers in southern Europe might have squeezed the geographic ranges of many temperate tree species below a critical threshold, driving them to extinction. The absence of mountain barriers in Asia and North America may have allowed temperate species to survive in southern refuges, accounting in part for the higher tree species richness in those regions.

The relative importance of colonization, speciation, and extinction rates in setting regional richness will vary depending on the taxon and the history of the region. Since regional and local richness are linked, an understanding of community assembly will require a new focus on these macroevolutionary processes. Fortunately, new phylogenetic methods involving sister group comparisons and other innovations have been developed by Mitter, Farrell, and others, which can distinguish among various macroevolutionary causes for regional and local richness variation. Such methods have given history and biogeography the consideration they deserve in some modern investigations of community structure (e.g., McPeek and Brown, 2000), but more work needs to be done. Community structure is undoubtedly influenced by contemporary processes as well, and distinguishing historical from present-day effects such as energy, local environment, and species interactions will be one of the biggest future challenges in this area.

2. Metacommunity Processes

Once species become part of the biota of a particular region, they can disperse among habitats, and as a result communities can be quite dynamic in space and time. The species within the region can thus be viewed as a species pool for a given local habitat. The species pool will be considerably larger than the number of species in any habitat for at least three reasons: (1) some species in the region will not be able to disperse to all sites because of colonization barriers or isolation-by-distance; (2) all habitats in the region are not favorable for all species; and (3) species can be driven locally extinct by species interactions, demographic and environmental stochasticity, disturbances, or other unfavorable changes in local conditions. It is of some interest to explore situations where species cut off by highly effective colonization barriers are not considered part of the pool for habitats from which they are isolated. The dynamic links between local and regional richness should thus be examined at a spatial scale where all species can reach all habitats over ecological time. Moreover, we should focus on a single habitat type, since looking at more than one habitat will confound regional effects with local environmental variation. This can generate artificial relationships between local and regional richness (Srivastava, 1999). The metacommunity within the landscape, in its simplest form, fulfills both of these criteria and thus represents an appropriate theoretical context in which to examine these links. The term metacommunity was first used by Gilpin and Hanski in 1991. The metacommunity can be thought of as a pool of species in a fragmented landscape of environmentally identical sites, each species behaving as a metapopulation in that its distribution among
sites in the landscape is determined by colonization and extinction. In this scenario, regional processes still determine the potential species pool, but now the effects of the pool on local richness are filtered through the metacommunity.

The simplest metacommunity model derives from Richard Levins' original 1969 equation for a single-species metapopulation:

\[ \frac{dp}{dt} = c_p(1-p) - m_p \]

Tilman and Lehman used this equation to construct a metacommunity model by writing independent equations for as many species as occur in the metacommunity (Tilman and Kareiva, 1997). The value of \( p_i \) is the proportion of local sites in the landscape occupied by the \( i \)th species, and \( c_i \) and \( m_i \) are the site-specific colonization and extinction rates, respectively. Thus, when \( \frac{dp}{dt} = 0 \), each \( p_i \) is set by a balance between colonization and extinction rates per site. The model assumes that all sites are identical. This assumption permits the examination of links between local richness and pool size without the confounding effects of local environmental variation. If \( p \) is defined as the mean of \( p_i \)'s for all species, then \( p \) becomes the average proportion of local sites occupied by a species. Alternatively, it is the average proportion of the metacommunity found at a particular site. Thus, local richness = \( p \) (landscape richness).

What this expression tells us is that if \( p \) is a constant, then local richness is a linear function of landscape richness, a pattern that has been called Type I or proportional sampling (Fig. 3). Proportional sampling predicts that matched habitats embedded in richer landscapes will always have richer communities, but that local richness will be less than landscape richness by a constant proportion. The slope of the relationship, \( p \), will be determined by the size of the pool balanced by the rate of species extinction at individual sites. In this simple model, species-specific colonization and extinction rates are assumed to be independent of pool size and the number of species at a site. Thus the model predicts the relationship between local and landscape richness in the absence of species interactions. Under these conditions, communities will be unsaturated and open to colonization from the species pool.

At least one recent study by Hugueny and Cornell (2000) has shown that the proportional sampling pattern in a real species assemblage can be predicted from colonization and extinction rates. Metacommunity models can be made more realistic by adding rescue effects, by adding provisions for variable population sizes among patches, by making habitats differentially suitable to different species, and by incorporating source–sink effects and habitat specialization. Such modifications may alter the details of the Type I curve, but they will not alter the conclusion that pool effects strongly influence community richness. Thus, for the purposes of conceptual distinction between saturated and unsaturated communities, the Levins model suffices.

The Levins model not only predicts the relationship between landscape and local richness; it also shows that the landscape filter constrains the species pool. Most obviously, landscapes that are smaller will have smaller species pools as predicted by the species–area relationship. More subtly, landscapes of a given area that are more highly fragmented will have smaller species pools because they suffer higher landscape-scale extinction rates. Fragmentation also reduces the average proportion of the pool \( (p) \) found at a local site by lowering per site colonization rates and increasing per site extinction. Thus any differences in landscape characteristics must be considered when estimating the species pool and evaluating the proportional sampling relationship.

If competitive interactions are added to the model, and it is assumed that competition leads to extinction rather than character displacement and speciation, then
increased competition can result in increased extinction rates and/or decreased colonization rates per species. As the species pool increases, competition could become sufficiently intense that colonization by a new species into the community would either fail or result in the rapid extinction of other species. Under this condition, further increases in the pool do not result in increases in local richness and the community becomes saturated with species. At saturation, the relationship between local and landscape richness levels off and becomes independent of the rate of colonization and the size of the species pool. This leveling relationship has been designated Type II (Cornell and Lawton, 1992). Species interactions are thus limiting local richness consistent with the Volterra–Gause perspective. Other dynamic models developed by Caswell and Cohen (in Ricklefs and Schluter, 1993) and Morton and Law (1997), which allow for dispersal, species interactions, and local extinction, also predict leveling off and saturation.

However, the spatial character of many dynamic models allows for realistic complexities that ameliorate the impact of species interactions on local richness. For example, if competition occurs only among close neighbors, and inferior competitors are better dispersers, then a potentially unlimited number of species can coexist locally (Lehman and Tilman, in Tilman and Kareiva, 1997). Other spatial models incorporating disturbance, limited dispersal, spatially local competition, and habitat heterogeneity also predict coexistence at high levels of richness in the face of competitive interactions (Cornell and Karlson, and Lehman and Tilman, in Tilman and Kareiva, 1997). Thus Type I relationships can still occur in the presence of intense competition.

It is important to point out that just because meta-community and other models predict proportional sampling or saturation under certain conditions, it does not mean that the Type I or Type II relationships need be explained exclusively by mechanisms operating at the landscape scale. The models simply represent theoretically plausible ways in which the pattern can be generated. Factors operating at other spatial scales can also produce Type I and Type II relationships. For example, suppose the scale of the analysis is expanded to the entire region. One reason to do this is that regions are easier to define than landscapes and thus more data on regional richness have been collected. Type I and Type II relationships are thus more conventionally represented as plots between local and regional richness (see Fig. 3). Under these circumstances, Type I relationships can result simply from dispersal limitation. That is, when regions of different species richness are compared, a constant proportion of the regional biota is unable to reach the habitat type of interest. Type II relationships, on the other hand, can be generated by historically stable communities in which all niche space is occupied and into which invasion is limited. In such situations, the community need not be particularly dynamic, need undergo little turnover in ecological time, and its species composition may bear the strong stamp of its historical development. Nevertheless, a Type I relationship would still be an indication that hard limits on local richness have not been reached even in the richest regions, whereas a Type II relationship would suggest saturation. The Type I and Type II relationships should thus be viewed as empirical patterns with multiple causes, but also as evidence that local richness is or is not limited by local factors.

II. TESTING FOR SATURATED COMMUNITIES

A. The Method

The preceding theoretical exploration suggests that one can test for saturation by examining the relationship between local richness and some reasonable estimator of the species pool. Regional richness has been the most commonly used estimator for the reasons stated earlier. To test for saturation, matched habitats are compared in different geographical regions of similar size that support different numbers of species. Habitats in richer regions are presumably exposed to richer species pools. Choosing regions of similar size should reduce any differential effects of colonization barriers that might generate differential dispersal limitation among regions (see Cornell and Lawton, 1992; Caley and Schluter, 1997). If the communities are unsaturated, local richness should increase steadily with increases in regional richness. The shape of the relationship can be linear (Type I) or curvilinear, but it cannot level off. Curvilinearity would suggest some resistance to invasion and thus a tendency toward saturation in richer regions, but that the limit to local richness has not been reached. If communities in the richest regions are saturated, then the curve will reach an asymptote and local richness becomes independent of regional richness (Type II).

The method assumes that matched habitats and species in different regions are similar in ways that are critical to species coexistence. This means that if there is the potential for saturation at some level of local richness determined by local environmental conditions and the characteristics of individual species, that level will be the same from region to region. However, even
if matched habitats are environmentally identical, some communities might exhibit multiple stable points and saturate at different levels, for example, due to differences in colonization order as shown by Drake. If the community is near saturation, multiple stable points might increase the variance around the putative asymptote but should not affect the average tendency for local richness to level off.

B. The Tests

Two recent surveys by Cornell and Karlson (1997) and Srivastava (1999) have evaluated the frequency of Type I and Type II relationships in a variety of species assemblages. The surveys were combined by Lawton (1999) to yield 38 papers. Some of the data were not analyzed strictly according to the protocol presented here, and in these cases interpretation of the pattern was conservative and based on common sense. By conservative estimate, there were at least 23 examples of Type I relationships (wood-boring beetles, tiger beetles, fig wasps, lizards, corals, plants, helminth parasites on introduced fishes, 6 examples of fish, 4 examples of plant-feeding insects, 3 examples of parasites, 2 examples of birds, and a variety of vertebrate taxa (birds, fish, mammals, reptiles) analyzed separately and in combination. By contrast, there were 15 examples of curvilinear relationships, and not all of these were Type II (saturating). The examples are classified as saturating (strong), weakly curved (weak), or uncertain (u) as follows: marine crustaceans (u), deep-sea gastropods (weak), tiger beetles (u), 2 examples of helminth parasites on fish (strong), helminth parasites on amphibians (strong), 2 examples of fish (u), 2 examples of birds (weak), 2 examples of mammals (strong), and 3 examples of higher plants (1 strong, 2 weak).

C. Caveats

Several methodological concerns about the saturation test have been raised by various authors. The most relevant of these to the present discussion are that various artifacts such as nonhomogeneous variance structures, insufficient sampling, and overestimates of the true species pool in richer regions sometimes exaggerate the curvilinearity of the relationship between local and regional richness. To the extent that such artifacts are present in some studies, true Type I relationships might appear curvilinear, and curvilinear but unsaturated relationships might appear to be Type II. The count of unsaturated patterns in the survey is thus a conservative and robust result, at least with respect to the presence of such artifacts.

D. Saturated or Unsaturated?

Given these caveats, at least it can be said that unsaturated patterns are common and widespread in ecological communities. Indeed, unsaturated patterns have been reported about twice as frequently as saturated ones. The survey thus confirms that local communities are often open to regional influences and have not reached any upper limit set by species interactions as predicted by the Volterra–Gause model. Those communities that have reached an asymptote might be saturated but have to be examined closely to rule out artifacts that might be responsible for the Type II shape. A Type II curve is not sufficient in and of itself to conclude that species interactions are limiting local richness. For example, helminth parasite communities on fish and amphibians appear to be saturated, but at least one expert opinion is that they are probably not (see Lawton, 1999).

The survey also supports the theoretical position that strong interspecific interactions are not always sufficient to generate a curvilinear or Type II relationship. Taxa that are known to experience strong interspecific interactions such as fish and birds show Type I or weakly curvilinear relationships that are characteristic of unsaturated communities. Although it is not certain that these particular assemblages were experiencing the strong interactions that are supposedly characteristic of these taxa, the results at least suggest that evidence for species interactions by itself might not permit generalizations about the effects of these interactions on broad patterns of community structure.

E. Experimental Support

Additional evidence from experimental introductions supports the survey results that communities are often unsaturated. Experimental manipulations of the species pool are only just beginning, but they are particularly useful because there is better control of confounding variables. In separate studies by Tilman (1997) and Robinson, Quinn, and Stanton (1993), seeds of native species were added to experimental plots containing different numbers of plant species and establishment was monitored. In the Robinson et al. study, California poppy was the test colonizer, and in the Tilman study, anywhere from 0 to 54 species were added to plots.
Neither study showed evidence of saturation; seeds became established and persisted in many plots. Unsaturation was dramatic in the Tilman study, as the number of species in the experimental plots continued to increase over the full range of species additions and the increases persisted for 4 years (Fig. 4). In other words, an asymptote characteristic of the Type II relationship was never reached. However, plots that were richer in resident species had lower establishment rates, suggesting some resistance to invasion.

The results of these experiments must be interpreted with caution, as they represent short-term responses to pulsed increases in the species pool. There are almost certainly time lags in the response of the community to species additions, and long-term monitoring will be required to confirm that the “invaders” have become established without driving “residents” extinct over ecological time. Nevertheless, pool manipulations offer a powerful probe for saturation and need to be expanded to other taxa and habitats to test the generality of these results.

III. MATTERS OF SPATIAL SCALE

A central issue in the exploration of saturation in communities is the spatial scale at which local richness should be measured. Ideally, a locality should be ecologically defined. That is, a scale should be chosen within which all species of interest are interspersed and can
potentially interact and within which the local environment is homogeneous. Since different species interact at different scales, and environments that are homogeneous for one species may be heterogeneous for others, the ideal locality will probably have indistinct boundaries. It may circumscribe the number of herbivore species associated with a host plant species, the number of insectivorous birds found in a patch of woods, or the number of flowering plant species associated with a serpentine outcrop. Local samples must be standardized in some way so that they are comparable among regions. Typically, the number of individuals or the unit area assessed is uniform, or local assemblages are sampled until the species/sampling curve levels off.

If regional richness is sufficiently high to engender saturation, it is not patently clear at which scale it should occur. Communities are hierarchically structured assemblages of organisms that may be saturated at one scale and not other scales because the intensity of dynamic coupling among species varies with the unit of study. Most comparisons of local and regional richness offer few clues about the relationship between hierarchical structure and saturation because local richness is evaluated at only one scale. Clearly, a more methodological exploration of hierarchical structure that involves multiscale sampling is required. A few studies have made limited attempts at a multi-scale analysis. Caley and Schluter (1997) measured local richness from distributional data of 10 different taxa at two local scales (1% and 10% of regional area) in various regions. All taxa fell along a Type 1 trajectory at both scales (Fig. 5). In a 1996 paper Kennedy and Guégan showed that parasite communities reached a hard upper limit of four species in individual cells whereas parasite richness in the cell population as a whole continued to increase steadily with regional richness. Finally, data on coral assemblages examined by Karlson and Cornell (2000) showed that local richness was less sensitive to regional richness in 1-m² quadrats than in 10-m line transects. In the latter example, the 1-m² quadrat is so small relative to the size of some coral colonies that local richness, particularly in very rich regions, could be limited simply by the number of individuals that can be packed into this small sample. In all three examples, only two local scales were examined, but for two of these examples, this was sufficient to show differential responses of local richness to changes in regional richness. Clearly, multiscale analyses will permit stronger inferences regarding saturation, or lack thereof, in communities. They will also be useful in defining the spatial arena within which local processes, which might in some cases limit local richness, should be sought.

IV. SYNTHESIS OF COMMUNITY AND REGIONAL PERSPECTIVES

A. A Thought Experiment

Since processes operating at scales larger than the local habitat (e.g., landscape or region) almost surely affect local richness, research emphasis must shift to these larger-scale processes. Only then can patterns of community assembly be completely understood. However, this shift does not imply that local processes should be ignored. Local- and larger-scale processes may both affect local richness and their relative influence must be determined. The advantages of this multi-scale perspective can be illustrated with a thought experiment.

Suppose we have two climatically similar regions with different regional richness due to historical factors. The Asian and European temperate forests discussed previously provide a good example. Suppose further that physically identical habitats of two types (e.g., sandy versus loamy soils) were transplanted into these regions and were allowed to achieve a steady state that showed no influence of initial colonization history. Once the steady state was reached, by how much would per locality tree species richness vary among habitat types and regions? The transplanted habitats would make it possible to partition the contribution to per-locality richness among processes operating at local and regional spatial scales. The design would also make it possible to evaluate interactions between regional and local factors and to examine mediation of species interactions by changes in the local environment.

B. Manipulations of Productivity and the Pool

Although the preceding experiment is possible in principle, it is likely to be difficult to carry out. Also, it is difficult to be sure that climatic conditions that may affect local processes are truly identical among regions. An alternative to habitat transplantation is a two-factorial manipulation of the species pool and local environmental conditions in the same region. For example, suppose some high-productivity lakes in a particular region had unusually low fish species richness. Is the low richness due to interaction mediation or pool limitation? Manipulations could be designed in which the entire fish species pool could be added to lakes of different productivity. In addition, productivity itself could be manipulated by adding fertilizer to particular lakes. Care would have to be taken that the fish were adapted
to live at the prevailing productivity levels. A full two-factorial design would make it possible to sort out pool effects, productivity effects, and pool X productivity interactions on local richness (see Section 1). If regional control of community structure is important, then pool effects or pool X productivity interactions should have important effects on local richness.

C. A Comparative Approach

In situations where experiments are intractable or when it is desirable to examine longer-term effects, the problem can be addressed using a statistical comparative approach. For example, Schluter and Ricklefs (in Ricklefs and Schluter, 1993) have suggested using multifactorial methods to partition the variance in local richness into components that can be explained by habitat differences within regions and species richness differences among regions. To the extent that local environments constrain local richness, species richness in similar habitats from different regions should converge relative to some hypothetical ancestral state of the community (Fig. 6). Detecting convergence is thus equivalent to measuring the variance component due to habi-
tat differences. Important regional effects on local richness will be detectable in the variance component due to differences in regional richness. Schluter and Ricklefs calculated variance components for 36 different studies and found strong convergence in many cases, consistent with significant local effects on local richness. Yet there were strong regional differences in richness within similar habitats as well. Using regression methods to study coral reef communities, Karlson and Cornell (1998) similarly found both local and regional effects to be important.

D. Conclusions

The results from experimental and statistical analyses confirm that both local and regional processes have important effects on local richness. Thus, not only must experimental work on local communities be continued, but investigations need to be expanded to encompass larger-scale processes as well. The Volterra–Gause image of an ecological system at equilibrium and independent of historical processes has undeniable appeal, and has engendered much productive research on community assembly. Nevertheless, integration of historical, biogeographical, and metacommunity processes with local interactions and environmental variation is essential for a complete understanding of richness variation in species assemblages.

Diversity, Community/Regional Level

GLOSSARY

background selection  Selection that takes place at loci other than that of interest. Such events can strongly increase the intensity of genetic drift and hinder the action of selection at a locus of interest. These effects are normally modeled by reducing the effective population size applicable to the locus of interest.

divergence  A fixed genetic difference between two species or populations, or the process of evolving such a difference.

effective population size  The size that a random mating population must have to experience the same intensity of genetic drift as a population of interest. The size can vary across genes due to changes in background selection across the genome.

functional constraint  A limit to the kinds of nucleotides or amino acids which can appear in a gene or protein without compromising function; often called "selective" constraints.

genetic drift  Random changes in gene frequency that occur when a finite number of zygotes or propagules is formed by random sampling gametes or genotypes from the previous generation to create the next generation.

mutation  A change in the nucleotide sequence of a DNA or RNA molecule.

nearly neutral mutation  A mutation whose population genetical dynamics are influenced by both genetic drift and selection.

neutral mutation  A mutation whose population genetical dynamics are influenced only by genetic drift.

nonsynonymous mutation  A nucleotide change in a coding region that changes an encoded amino acid.

polymorphism  A genetic difference between two or more individuals of the same species; to exclude new mutations from the definition, the underlying mutations are required to segregate above an arbitrarily set minimal frequency.

replacement  Divergence due to a change of an amino acid in a protein, or the process to evolve such a change.

selection  Differential reproduction within a set of genes, individuals, groups, etc. caused by differential performance in fitness determining tasks. The appropriate unit of selection (gene, individual, or group) is determined by the level at which the causation of the fitness differences must be described (interactions or performances at the level of genes, individuals, groups, etc.).
substitution Divergence due to a change of base in a DNA sequence, or the process to evolve such a change.

synonymous mutation A nucleotide change in a coding region that does not change the encoded amino acids.

THIS ARTICLE DEALS WITH MOLECULAR DIVERSITY at the DNA and protein levels and will concentrate on diversity that is genetically heritable. Therefore, molecular diversity shown by other macromolecules and/or that is not heritable will not be discussed. However, this does not imply that the latter diversity is biologically insignificant. Indeed, much of molecular diversity is of this kind, with secondary metabolite profiles in plants and antibody diversity generated via mutation and genetic rearrangements in somatic cells of vertebrates being two outstanding examples. We discuss molecular diversity patterning and causation primarily at the level of single genes and genomic regions. Therefore, important aspects of molecular diversity that concern higher level genomic structuring and evolution will not be treated systematically (e.g., gene duplication, multigene family evolution, concerted evolution, genome size evolution, and mammalian isochore structure).

The article will first deal with DNA and protein diversity within populations and among populations of the same species (molecular polymorphism) and then with that caused by genetic differentiation between species and higher taxa (molecular divergence). Such order is justified because visualizing diversity in this way helps in understanding the evolutionary and population genetic forces and processes that generate it.

The information presented here is almost exclusively drawn from knowledge gathered by molecular evolutionary biologists and molecular population geneticists. Molecular evolutionary research aims at characterizing the degree and forms of molecular divergence, at clarifying how such differentiation takes place, and—by taking advantage of the former—at reconstructing the history of DNA sequences and proteins and the genealogical relationships among extant and sometimes extinct organisms. Molecular population genetics studies the form and extent of molecular polymorphism and tries to identify the forces that pattern it.

I. INTRODUCTION

Phenotypic differences between organisms are due to environmental and genetic differences, and the latter are the result of genetic divergence or polymorphism. When due to divergence, genetic differences often can tell us about the physical and geographical environment in which organisms evolved. When due to polymorphism, they can tell us about the ecological arena that is shaping the genetic constitution of a species (gene pool). Realizing that polymorphism is a common and striking phenomenon in the living world is not only important when trying to make sense of molecular diversity. Indeed, the transition from typological (essentialistic) to "variational-populational" thinking was a major contribution of the Darwinian revolution to biology.

Measuring genetic diversity within and between species is a long-standing interest of biologists. However, this only became possible in a systematic way in the 1960s when novel techniques from molecular biology (protein sequencing and enzyme electrophoresis) began to be applied to the study of evolutionary and population genetic questions. These techniques opened the possibility to study variation at the molecular level (allozyme variation and amino acid sequence divergence) and gave birth to the fields of molecular population genetics and molecular evolution. The availability of protein sequences from various taxa triggered sophisticated studies of the forces driving protein evolution and led to the first reconstructions based on protein sequence data of historical relationships among organisms (phylogeny). However, protein sequencing could not be used for quantitatively oriented studies of polymorphism because of its laboriousness. Electrophoretic studies of variation were carried out in hundreds of taxa and confirmed less conclusive previous observations that hinted at the presence of large amounts of genetic variation within populations. Electrophoresis, however, often failed to detect some amino acid variation so that it could not deliver data of sufficient quality to study the nature of the evolutionary forces maintaining variation and the importance of such variation for the process of adaptation.

The advent of DNA sequencing in the 1980s eliminated resolution problems and made it possible to describe exhaustively the genetic variation segregating within gene loci. Before DNA studies this was not possible, and in fact investigators developed and tested models that predicted patterns for electrophoretic variation segregating at many loci because only such data could be produced in statistically analyzable counts. The shift to DNA studies allowed researchers to quantify conclusively not only amino acid polymorphism but also coding region variation that does not change the encoded amino acids (synonymous variation) and variation in noncoding regions, both of which were found to occur
in copious amounts. This increased drastically the amount of data obtainable from a single locus and thus the number and the statistical quality of contrasts among classes of variation subject to arguably different functional constraints. New and possibly ultimate imagery was developed to describe the processes shaping DNA-level variation within and between populations and new, often more powerful modeling approaches were developed and/or given a more solid empirical grounding (e.g., coalescence and maximum likelihood estimation of genetic distances). However, despite all the technical and conceptual advances in describing and quantifying molecular variation, we still know very little about the genetic basis of adaptation and about the relationship between genetic and phenotypic differences among organisms.

II. THE GENERATION AND MAINTENANCE OF GENETIC DIVERSITY

There are three main sources of genetic variation in natural populations: mutation, recombination, and migration. Mutation is the only mechanism that can generate variation in a genetically homogeneous population since recombination and migration only shuffle and shuffle around preexisting variation, respectively. Mutation is therefore the original source of all genetic variation.

In order to understand the evolutionary and population genetic forces patterning genetic variation, it is useful to consider variation at two main levels: within and between species. The first level constitutes the polymorphism component of genetic diversity, which can also be considered at finer levels if gene flow is structured within the species under study (“geographic” structure). Within sexual populations this type of diversity is more or less freely combined each generation to form individual genotypes. The second level constitutes the divergence component of genetic diversity, which can also be considered at multiple levels depending on how closely related are the species under study. This type of diversity consists of fixed differences between species and is only exchanged in extraordinary circumstances (horizontal gene transfer and introgression).

The patterns of genetic variation within species arise from the combined action of two main sets of processes: (i) a molecular-level origination process in which a mutation in a DNA sequence arises and (ii) a population-level “fate” process that determines whether the mutation is quickly eliminated from the population or enters the pool of intraspecific variation becoming a polymorphism. The fate process also includes the possibility that the mutation becomes fixed in the population, i.e., part of the divergence component of diversity. If a new mutation is passed on to the next generation of individuals, its final fate depends on the stochastic error produced when creating a finite number of zygotes or propagules by sampling gametes or genotypes from the previous generation (random genetic drift), on demographic forces such as gene flow and changes in population size, as well as on the deterministic action of natural selection if the mutation is deleterious or advantageous.

III. DIVERSITY AS POLYMORPHISM

What is the quantity and the quality of genetic variation found in natural populations? What are the evolutionary forces responsible for the observed patterns of variation in natural populations? What is the meaning of that variation? What is the relationship between adaptive changes, phenotypic changes, and extant genetic variation? These are some of the questions asked by evolutionary geneticists. The following sections provide examples and summarize the current answers to the first two questions but do not elaborate on the last two questions given the un conclusiveness of the current knowledge on the subject.

A. Empirical Observations

Fruit flies (Drosophila sp.) are by far the best studied group of organisms with respect to their patterns of heritable molecular diversity. Two randomly chosen homologous sequences of Drosophila melanogaster show on average four nucleotide differences per kilobase (kb). A comparison of two full haploid genomes (i.e., including the X chromosome) would give a total of $7.2 \times 10^5$ nucleotide differences over the 180-Mb of a typical haploid genome on average, of this species. Drosophila simulans, a closely related species, has twice as much variation: eight differences per kilobase and an average of 1 million nucleotide differences between any two haploid genomes (the D. simulans haploid size is 130 Mb).

Studies of other taxa are limited to few genes or genomic regions but nevertheless allow interesting contrasts. Humans, for instance, have less variation than fruit flies (one difference per kilobase), but two average human haploid genomes could differ at more nucleotide sites (3.4 Mb) because the human haploid genome size is much larger (3400 Mb). On the other hand, the few
nuclear loci studied to date in the common and pygmy chimps (Pan troglodytes and P. paniscus) show about three times more nucleotide variation than do the homologous loci in humans. In plants, one of the genes encoding the enzyme alcohol dehydrogenase (Adh1) shows levels of polymorphism that range from 1.8 differences per kilobase in wild barley (Hordeum vulgare) to approximately 18 differences per kilobase in maize (Zea mays). In contrast, the homologous gene in D. melanogaster shows an average of 6.5 differences per kilobase. These quantities describe more or less the typical range of DNA polymorphism in natural populations.

The question about the quality of the variation (i.e., about the functional consequences of the observed nucleotide polymorphisms) is normally approached by extrapolating from a priori knowledge about the genetic code and from the conservation of certain nucleotides and nucleotide motifs in noncoding regions. For instance, amino acid changes are counted separately from synonymous changes, and changes violating the phylogenetically or functionally determined canonical motifs of regulatory sequences are distinguished from those that do not. With respect to identifying selective pressures affecting different variants, the frequency pattern of mutations (are variants rare or common?) can be very informative. For instance, an indication of deleteriousness is the occurrence in different samples of a certain kind of mutation only at low frequencies (i.e., in only one or few of the sampled individuals).

Drosophila data show that in noncoding regions (flanking regions and introns) there is more variation than in coding regions (2.5 and 2.4 times more variation in D. melanogaster and D. simulans, respectively) and that synonymous polymorphism is higher than noncoding polymorphism (1.2 and 1.6 times higher, respectively), and higher than amino acid polymorphism (2.7 and 7.6 times higher, respectively). Most amino acid variation tends to be found at low frequencies and so are silent changes away from the major (preferred) synonymous codon within a codon family (i.e., toward minor, preferred codons) in genes with biased usage of synonymous codons.

These observations about patterns of variation can be very informative when asking questions such as the following about the nature and sometimes the magnitude of the evolutionary forces generating the patterns: Why do some species have more variation than others? Is it due to differences in the rate of origin of mutations? To differences in the size of their populations? To recent evolutionary, demographic, and ecological events? To the species’ distributions over geographic space? To their breeding system? To the genomic context in which the mutations occur (e.g., the intensity of recombination and of deleterious mutation in and around the studied locus)? The latter possibility has been shown to apply in Drosophila by two recent studies that found a positive correlation between levels of variation and the rate of recombination.

B. Molecular Biological Considerations

The mutation process is known to be affected by physiological and life history characteristics of the organism which affect the rate and accuracy of DNA replication (generation time, number of divisions before gametogenesis, sex, and age) and by factors that increase damage to DNA (metabolic rate, age, transcription rate, and the frequency and degree of packing and unpacking of chromosomes for expression). DNA damage is caused by exogenous and endogenous agents. Exogenous agents include UV light, ionizing radiation from X-rays, heat, alkylating agents, and hydroxyl radicals originated by the interaction of ionizing radiation with water. Endogenous agents include oxidant by-products of normal metabolism. Changes generated by endogenous agents cause the highest fraction of DNA damage. In human cells, oxidants damage between 10⁴ and 10⁵ nucleotide sites every day. Such damage would be extremely deleterious were it not for the presence of enzymes involved in finding and repairing it. Of the five major types of DNA mutations—substitutions, deletions, insertions, inversions, and duplications—nucleotide substitutions and single base pair deletions or insertions (all called point mutations) account for 85% of the mutation events.

With the exception of macromolecular events such as chromosomal rearrangements, most mutations are the result of errors made by enzymes involved in DNA replication and repair. Replication errors are often due to the incorporation of noncomplementary nucleotides by the DNA polymerase and incorrect subsequent proofreading by the same enzyme. The latter process, however, is normally extremely effective at lowering the error rate by a million-fold relative to the intrinsic misincorporation rate of the polymerase. Table I shows the range of mutation rates observed in several organisms.

C. Cytological and Ontogenetic Considerations

In viruses, prokaryotes, and unicellular eukaryotes—with the notable exception of protists such as Parame-

D. Factors Influencing the Fate of Mutations

Patterns of molecular diversity other than those created by a continuous flow of short-lived mutations which remain unique to the individuals in which they arise can be very striking. For instance, some of the loci encoding the antigen-presenting major histocompatibility complex (MHC) in humans show extremely high levels of amino acid and synonymous polymorphism as well as many alleles segregating at intermediate frequencies. On the other hand, loci in the human Y chromosome show little polymorphism and mainly low-frequency mutations.

In general, patterns of polymorphism are determined by mutation pressure, genetic drift, and natural selection. The effectiveness of the action of the last two forces depends on the effective population size (see Glossary) and on the fitness effect of the mutation involved. In particular, the transmission genetical sampling effect at the basis of genetic drift phenomena increases in strength with decreasing population size and this in turn hinders the deterministic action of selection.

The patterns of variation of selectively neutral mutations are totally determined by genetic drift, population size, and the rate of mutation to neutral variants. For selected mutations both drift and selection can affect the patterns. In the case of strongly deleterious mutations, the observed pattern is one of mutations unique to each individual and none segregating at high frequencies because such mutations remain in the population for only very few generations. When a steady state is reached between the number of new mutations being produced by mutation and those being removed by selection, one speaks of a mutation—selection balance. There should not be any observable polymorphism patterns for strongly favorable mutations because such mutations are normally fixed soon after being introduced in the population (if they are not immediately lost to drift) and practically do not participate in polymorphism. However, favorable mutations can be maintained at intermediate frequencies, e.g., when the heterozygote has higher fitness. In this case, one speaks of a balanced polymorphism (as in the MHC case previously mentioned). For weakly selected mutations, genetic drift and selection are important. Note that the previous considerations are mainly applicable to recombining populations because in asexual populations and in cases with very weak selection and low recombination intensity, situations can arise that require considering patterns and forces at the level of the whole genome or of long stretches of the genome.

E. Models of Molecular Evolution

The main models that make predictions about the patterns of polymorphism and divergence are the neutral
theory proposed in the late 1960s by M. Kimura, the nearly neutral theory proposed in the early 1970s by T. Ohta, and a series of models of natural selection developed by J. Gillespie during the past two decades. The first two models emphasize the importance of genetic drift and mutation, whereas the latter group of models stress the role of natural selection. All models agree that the vast majority of newly arisen mutations are deleterious, but they differ greatly in their assumptions about the relative proportions of neutral and favorable mutations that participate in polymorphism and divergence.

1. Neutral Theory

Kimura's neutral theory postulates that both the fixation of genetic differences between populations and the patterning of genetic variation within populations are the result of random changes in the frequency of neutral alleles driven by genetic drift. This model assumes that most new mutations are either deleterious or neutral and that advantageous mutations arise quite infrequently and are quickly fixed or lost to drift so that they are not important for polymorphism. Most of the theory's predictions for polymorphism patterns assume mutation–drift equilibrium, i.e., that the rate of allele loss to drift is balanced by the production of new alleles by mutation. The predictions therefore apply only when the population size and the mutation rate have been constant for a long period of time.

The theory predicts that the amount of polymorphism within a population is proportional to the effective population size \( N_e \) and the mutation rate \( \mu \). Nucleotide polymorphism is normally expressed in terms of the parameter \( \theta \) \( (= 4N_e \mu) \), which can be interpreted as the average number of differences per nucleotide site between two alleles randomly chosen from the population. This divergence is the result of nucleotide mutations that have accumulated since the two alleles last shared a common ancestor. Theory has shown that the expected time back to this ancestor for an autosomal locus in a diploid is \( 2N_e \) generations so that when each allele has been evolving independently for \( 2N_e \) generations, the expected number of nucleotide differences between them is \( 2 \times 2N_e \) times the mutation rate \( \mu \), i.e., \( 4N_e \mu \).

The neutral theory explains the fact that different genes and regions of the genome show different levels of polymorphism by assuming that the neutral mutation rate varies among such regions and genes because they are under different functional constraints. Recent simulation work has led to a restressing of the realization that the effective population size can be reduced by selection against deleterious mutations at linked and unlinked sites ("background selection"). This effect can compel neutral polymorphism to change drastically across regions that differ in recombination intensity and deleterious mutation production.

2. Nearly Neutral Theory

Ohta's model, also known as the slightly deleterious allele model and considered by many to be the "dominant paradigm for molecular evolution," was proposed in the early 1970s in order to account for two observations that could not be explained by the neutral model: the generation time effect for DNA divergence and the lower than expected levels of protein variation in natural populations. The model deviates from the neutral theory mainly because it assumes (i) that most observed molecular variation is slightly deleterious, (ii) that mutation rates are correlated with the generation time (g), and (iii) that the rate of molecular divergence for slightly deleterious alleles is inversely proportional to \( N \). The nearly neutral theory is biologically realistic because it proposes plausible correlations of population genetic parameters such as \( g \) and \( N \) with the origination and fate processes of molecular evolution, and because it avoids the unrealistic assumption of complete neutrality for most variation participating in polymorphism and divergence.

Slightly deleterious alleles, also called weakly selected alleles, are defined as those with selective coefficients close to the neutral boundary \( (s \approx 1/N) \) and are seen as major contributors to polymorphism and divergence in natural populations. The neutral theory stresses that the fate of neutral variants depends only on random drift, whereas the slightly deleterious model builds on the fact that the fate of slightly deleterious variants depends on the joint action of both drift and selection. Which of these two processes is more important depends on the effective size of the population because the efficacy of selection in removing slightly deleterious variants and fixing advantageous ones is higher in larger populations. In smaller populations slightly deleterious mutations can increase in frequency and become fixed by genetic drift, but in large populations selection prevails and eliminates them quickly. Therefore, the nearly neutral model predicts that if most of the observed variation in natural populations is slightly deleterious, polymorphism patterns should be dominated by rare variants.

The lack of correlation between genetic variation and population size (especially in large populations) was explained by this model with the argument that when divergence and variation involve mainly slightly
deleterious alleles, the amount of diversity in a population should be proportional to \( N \) but nevertheless reach a plateau when \( N \) is large enough for selection to impede that slightly deleterious variants increase in frequency. A main problem with this interpretation is that in organisms with very large population sizes one would not expect any variation if most polymorphism is due to slightly deleterious variants (at least no amino acid polymorphism), which is clearly not the case.

3. Selection Models

Gillespie proposed and developed a series of selection models that are less terse in their assumptions than the neutral and nearly neutral models but that can account for most of the empirical observations about molecular polymorphism and divergence. The models assume that balancing and episodic selection dominate the patterning of divergence and polymorphism at the molecular level. They predict that fluctuations of the environment can lead to the maintenance of polymorphism by balancing selection and, in the right circumstances (when the selective advantage of an allele is greater than the variance of the fitness effects of the alleles at that locus), to the fixation of favorable alleles. The models assume fitness effects that are underdominant, overdominant, or that change in a random environment (SAS-CFF model) or in a temporally fluctuating environment (TIM model). The addition of environmental variability is biologically realistic since the existence of fluctuations in the fitness value of segregating alleles due to changes in the environment over ecological timescales is quite plausible. These models predict patterns of polymorphism similar to those predicted by the neutral models, which makes hypothesis testing very problematic.

F. Statistical Tests on Molecular Polymorphism

Of all the models of molecular evolution, only the neutral theory makes simple quantitative predictions about expected levels and patterning of genetic polymorphism. This fact makes the neutral model a very popular null hypothesis against which to test the importance of other evolutionary forces in shaping patterns of polymorphism. There are two basic families of statistical tests for neutrality: (i) models that test neutrality using polymorphism data from a single locus and (ii) models that test neutrality using polymorphism and divergence data.

The data required for the single locus tests are homologous DNA sequences collected from individuals of a single species. This family of tests compares three estimates of the neutral parameter \( \theta \), which equals \( 4N\mu \) for an autosomal locus in a diploid. The three estimates are straightforwardly calculated from (i) \( \pi \), the average number of pairwise differences between the sampled alleles which should be equal to \( \theta \); (ii) \( S \), the number of polymorphic sites in the sample; and (iii) \( \eta \), the number of mutations present in only one of the sampled alleles (singletons). Under neutrality the values of these estimates should be the same. The tests therefore ascertain whether departures from zero of the differences between any two of these estimates are statistically significant for the sample at hand.

Tajima, for instance, proposed comparing the values of \( \pi \) and \( \theta \_ {\text{e}} \) (\( \theta \) estimated by \( S \)) using his statistic \( D \), which is the difference between \( \pi \) and \( \theta \_ {\text{e}} \), normalized by dividing the statistic by a factor proportional to the variance of the difference. Negative values of \( D \) are expected in the presence of purifying selection or following a purging of variation from the region by selection driving the quick fixation (1) of a new mutation or (2) a rapid increase in the frequency of an allele previously present at a lower frequency (selective "sweep"). Positive values of \( D \) are expected with balancing selection and population subdivision.

Although the patterns predicted by the neutral theory are always used as null hypothesis, the patterns produced by the two main kinds of selection regimes and/or events (sweeps and balanced polymorphism) have also been described thoroughly, and it has sometimes been striking how well they match the data. For instance, selective sweeps tend to reduce neutral variation in regions linked to the selected site. This "hitchhiking" effect on neutral variation (in this case, non-hitchhiking because most variation does not manage to get a "ride") is more pronounced in zones with low recombination. Balancing selection increases the levels of variation over the neutral expectation in the sites adjacent to the balanced site by making the times to the common ancestor at these linked sites more similar to that of the balanced site (i.e., to the time since the establishment of the polymorphism) than to the neutral time at unlinked sites. If the polymorphism is older than \( 2N \) generations, one should observe an increase in neutral variation in the region of the balanced site relative to the neutral expectation. Another phenomenon that can affect the level, but much less so the pattern, of neutral variation is "background selection." This effect and regular sweeps may account for the low levels of polymorphism observed in regions with low recombination.
IV. DIVERSITY AS PHYLOGENETIC DIVERGENCE

How could genes, proteins, and genomes become so different, and what limited how different they could become? Are there heterogeneities in the rates of divergence among different proteins, genes, and genomic regions? Do molecules from different organisms evolve at different rates? What are the mechanisms of nucleotide and amino acid substitution? Can we infer the genealogical relationships among different organisms from molecular data? Can we use molecular divergence data to date evolutionary events? These are some of the questions addressed by researchers in the field of molecular evolution. The following sections provide examples and summarize the current answers to the first three questions, i.e., those most relevant to understand the evolutionary dynamics of molecular diversity.

A. Some Empirical Observations

One of the main patterns of divergence that have been described by protein and DNA sequencing studies is that rate of amino acid replacement in different kinds of proteins and in different organisms are extremely variable (Table II). Histone H4, a protein involved in the packaging of DNA in chromosomes, is a striking case of an extremely conserved protein. Comparisons of H4 histones from plants and mammals show that only two amino acid replacements, over the 100 sites compared, have taken place since the two groups last shared a common ancestor about 1 billion years ago. On the other hand, viral envelope proteins, which are under constant challenge by the host immune system, change at extremely high rates—between 1 million to 10,000 times faster than the fastest mammalian protein (interferon-γ).

Table II also shows that rates of substitution at synonymous sites are higher than rates at nonsynonymous sites. This is expected because amino acid changes often disrupt the function of the protein, whereas synonymous changes are less likely to have comparable consequences. This explanation is corroborated by the observation that noncoding regions and pseudogenes (deactivated genes) evolve with rates similar to those of synonymous changes. However, in several proteins amino acid replacements occur more frequently than

*Drosophila rates are from comparisons between the obscura and the melanogaster groups (after Li, 1997).*
synonymous substitutions, e.g., in the antigen recognition site of the HLA loci in humans, in two fertilization proteins of abalone, and in proteins involved in male reproduction (Acp26Aa) or associated with male sterility (OdsH) in Drosophila. In the latter locus, for instance, amino acid changes have occurred in less than 1 million years than during the previous 700 million years. The rapid evolution of this gene is likely due to a change in function.

Similarly, different parts of a protein (e.g., protein domains) can diverge more readily than others. A classic example is the hinge pocket and the surface regions in hemoglobin α and β, which show a 10-fold difference in their rates of amino acid divergence. A similar situation occurs in the mitochondrial cytochrome oxidase II, whose transmembrane domain evolves at a much faster rate than the rest of the protein.

Another major pattern evidenced by the data is that different taxa can evolve at quite different rates (lineage effects). For instance, a survey of substitution rates in 54 mammalian genes shows that rodents tend to have higher rates of synonymous divergence than primates, but their nonsynonymous rates are not significantly different. Similarly, sharks show a seven-fold reduction in rates of silent rRNA evolution with respect to primates. Finally, endosymbiotic bacteria associated with aphids show higher rates of amino acid replacement than do closely related free-living strains.

B. The Substitution Process

The fixation of new mutations gives rise to the divergence component of genetic diversity. This process describes how a new allele replaces the previously most common allele in the population, thereby becoming the common ancestor of all alleles at that locus. The dynamics of the substitution process are determined (i) by the rate of origination of new mutations in the population, and (ii) by the probability of fixation of such mutations. The main evolutionary forces affecting this process are mutation, genetic drift, and selection, with their relative importance differing for neutral, weakly selected, and strongly selected mutations.

Neutral autosomal mutants are produced in a diploid population with rate $2N\mu$ per generation, i.e., the number of new mutations produced each generation is equal to the product of the number of genes copies in the population that can mutate, times the mutation rate to neutral alleles per gene per generation $\mu$. The same result applies for selected mutations if we let $\mu$ become the rate of mutation to strongly selected or weakly selected alleles.

The probability of fixation of a mutation depends on the selective advantage or disadvantage of the mutation, on the population size, and on the initial frequency of the mutation. For a newly arisen autosomal mutation, the initial frequency is $1/2N$ in a diploid population, which for the neutral case equals the probability of fixation of the mutation (since any of the $2N$ alleles present at any given moment can become the common ancestor of all alleles in the population some time later). For a nonrecessive mutation with selective coefficient $s$ close to $1/N$, the probability of fixation is about $2s/(1 - e^{-2Ns})$. If the value of $s$ is positive (advantageous mutant) and the population size is large such that $Ns \gg 1$, the fixation probability is twice the selective advantage of the mutant ($= 2s$). Even in this case, however, genetic drift is the main determinant of the fate of new mutations (e.g., 80% of mutations with $s = 0.1$ are lost to drift). For a deleterious mutant (negative $s$) the fixation probability is lower than that in the neutral case and is practically zero for strongly deleterious mutations.

The rate of substitution equals the average number of new mutant alleles entering the population in each generation times the probability that one of them will fix. For a neutral allele, this equals $(1/2N) \times (2N\mu) = \mu$, i.e., the rate of substitution of neutral alleles equals the mutation rate. For selected mutations the rate of substitution equals $4N\mu$, and is therefore dependent on the mutation rate to favorable selected mutations, the population size, and the selection coefficient of the mutant. It is easy to see that for the neutral rate of substitution to remain constant across different populations it suffices that the neutral mutation rate does not change. For selected mutations, however, the substitution rate could vary much more since its constancy requires that three parameters do not change or that each varies in ways that balance changes in the others.

C. Models of Molecular Evolution

From their conception, most theoretical models of molecular evolution dealt with both divergence and polymorphism from a population genetically explicit perspective. In the following sections, we present the predictions for patterns of divergence for the most relevant models (for polymorphism, see Section III).

1. Neutral Theory

Kimura showed that genetic divergence at neutral loci should increase over time due to the fixation of neutral mutations by random drift at a rate that equals the neutral mutation rate $\mu$. This predicted constancy in the
rate of substitution matched the empirical observations showing constant rates of amino acid substitutions per year for different proteins in a wide range of vertebrate lineages that led Zuckerkandl and Pauling to propose the molecular clock hypothesis in the early 1960s. The match is often viewed as positive evidence for Kimura's neutral theory, but this is a misunderstanding since selection models can also produce clock-like divergence.

The observed differences in rates of evolution among different genes and the heterogeneity of divergence rates in different regions of a gene are explained by the theory as being the result of differences in the fraction of all mutants that are neutral for each given gene or region (i.e., different functional constraints).

2. Nearly Neutral Theory

Ohta's model assumes that most molecular diversity is slightly deleterious, and predicts that the rate of production and fixation of neutral mutations is negatively correlated with organismal generation time (generation time effect), and that the rate of divergence for slightly deleterious changes is inversely proportional to the population size. The negative correlation between generation time and mutation rate is expected when mutations occur mainly during DNA replication and the number of germinal cell replications per generation is the same across different organisms. The germinal cells of short-lived organisms should indeed experience more DNA replications per year than those of long-lived organisms so that more neutral mutations can be produced in short-lived organisms. This assumption corresponded well with observations from divergence studies from the early 1970s based on DNA hybridization that showed a strong generation time effect for noncoding DNA evolution. The generation time effect can be obscured in comparisons among distantly related organisms when they differ in developmental mode and germline ontology (see Section III).

An important contradiction that this theory tried to resolve was that protein evolution appears to be clock-like, whereas noncoding DNA evolution shows a generation time effect. The neutral model explained the former by asserting that most amino acid replacements are neutral. The nearly neutral model asserted that protein divergence is mainly due to the fixation of slightly deleterious alleles, so it had to resort to postulating that generation time is inversely proportional to population size in order to account for the constancy of amino acid replacement rates. It was argued that small organisms have higher mutation rates per year due to their shorter generation times but that due to their larger population sizes, they fix slightly deleterious amino acid changes less readily. On the other hand, organisms with longer generation times have lower mutation rates but smaller population sizes so that they fix slightly deleterious mutations more easily. Therefore, the fact that in actual populations generation time correlates negatively with population size lets the rate of amino acid divergence appear clock-like. Although this negative correlation initially failed to be corroborated, recent studies have shown it to hold across different taxonomic levels.

A major problem with this theory concerns divergence: slightly deleterious variants cannot accumulate indefinitely because they would decrease the fitness of the population, thereby giving new favorable mutations a major role in the process. Additionally, in large populations no divergence should occur because in them selection should be efficient enough to eliminate most slightly deleterious alleles.

3. Selection Models

Divergence data led Gillespie to propose his selection models. He showed that there is excessive variation in amino acid divergence rates in different mammalian proteins using the index of dispersion $R(t)$, which is the ratio of the variance in substitution rate to the mean substitution rate. The index ranged between 2.5 and 7.5, whereas the neutral theory predicted it to be approximately 1.0 (as expected for a simple Poisson process). These high values of $R(t)$, which were not confirmed in a recent Drosophila study, led Gillespie to propose that the process of divergence is characterized by bursts of substitutional activity during which alleles previously segregating at high frequencies become rapidly fixed by selection, followed by quiet periods with little substitution and long-lived intermediate frequency polymorphisms. This still allows for a molecular clock if the periods of bursting and stasis succeed each other more or less regularly. One speaks in this case of an episodic molecular clock. Nevertheless, neither these models nor the neutral and nearly neutral models can completely account for the excessive variance of the rate of amino acid replacement in mammals. Improvements of these models will include increasing the time frame over which the fitness effects of mutations change or fluctuate. However, the complexity of the models has already reached the point that they can fit almost any observation, which compromises their value for hypothesis testing. At this point, one will have to assess the plausibility of their assumptions rather than the accuracy of their predictions.
V. COMBINED PREDICTIONS FOR DIVERGENCE AND POLYMORPHISM

Two tests based on the mutual compatibility of divergence and polymorphism patterns have been developed and used with much success to test the neutral theory. When they reject neutrality, outside information can help in further identifying the forces that might have caused the rejection. The Hudson–Kreitman–Aguade (HKA) and the McDonald–Kreitman tests focus on the positive (1) correlation between the (2) amounts of polymorphism and divergence expected under neutrality (given the linear dependence of both patterns on the mutation rate).

The HKA test compares the correlation between polymorphism and divergence at two or more loci. Its rationale is that if loci have different neutral mutation rates, their rates of divergence and levels of polymorphism should be equally affected. Selection is therefore inferred when the ratio of polymorphism to divergence varies too much over loci, a conclusion that requires sophisticated corrections to deal with the fact that, due to stochastic reasons, different loci can have different levels of polymorphism if they are not totally linked.

The McDonald–Kreitman test uses a similar contrast but concentrates on “loci” that are interspersed with each other over the sequence, thereby avoiding the need for the previously discussed corrections and drastically increasing the statistical power. This test can be applied to contrast silent and replacement variation, or unpreferred vs preferred silent changes, but it has mainly been used to compare the former within and between species under the assumption that these two kinds of variation are homogeneously distributed along the coding region studied.

Rejections of neutrality with both tests can be due to departures at the divergence or at the polymorphism level. For instance, an excess of amino acid polymorphism relative to amino acid divergence should be observed if variation is slightly deleterious. However, this “excess” could very well be due to a deficiency in silent polymorphism and/or an excess in silent divergence. If the ratio of amino acid replacement to silent substitution is significantly greater than the ratio of replacement to silent polymorphism, one could infer that natural selection has been fixing amino acid mutants beyond the neutral expectation, but again this could be due to a deficiency in amino acid polymorphism and/or in silent divergence. This is why outside information must be used to identify the causes of a rejection of neutrality by these tests.

VI. OMITTED DIVERSITY PATTERNS

The patterns of molecular diversity presented previously were originally studied in order to test hypotheses about abstract evolutionary and population genetic dynamics. For this reason, they are not necessarily representative of the phenomenon of molecular diversity in a more comprehensive molecular biological, natural historical, and organism–evolutionary sense. This explains, for instance, the lack of information about the evolutionary dynamics of molecular diversity with developmental consequences. Although biologists are well aware that this kind of diversity may be extremely important in an organism–evolutionary sense, the current lack of knowledge about it makes it very unsuitable for evolutionary and population genetic research that focuses on hypothesis testing. The concentration on variation suitable for hypothesis testing also explains this article's lack of an extensive presentation of many important molecular biological and biochemical constraints on diversity patterns. For instance, the dinucleotide motif T/A ("T" is the codon boundary) is very under-represented in most coding regions of Drosophila, yeast, and humans, but no research has been done on how it constrains molecular diversity patterns. However, this constraint is quite likely to affect variation patterns in more coding regions than the high codon usage biases shown by most highly translated genes. It is an important task to increase our knowledge of molecular diversity with respect to molecular biological constraints and in the natural historical and organism–evolutionary sense.

VII. PROBLEMS OF THE MODELS PRESENTED

Most of the neutrality- and selection-based modeling of polymorphism and divergence is based on single-site approaches, and it was not until the 1980s that linkage effects began to be considered. In models with selection, single-site results which assume that no further concomitant mutants are segregating are the standard, and the few efforts to deal with many concomitant mutations assume multiplicative fitness effects of mutations, i.e., that fitness is \((1 - s)^i\) when one carries \(i\) mutations.
The latter assumption is made out of convenience and lack of clear alternatives but is not justified a priori nor has it been justified a posteriori. It is indeed not clear how selection acts on, for example, synonymous or insertion/deletion variation, and one cannot exclude that it acts at the level of the total individual genotype via a possibly complex epistatic relationship between the number of mutations and fitness. Similarly, it is very likely that the assumption that silent variation is weakly selected \( (s = 1/N) \) is incorrect because in fact too many species with too disparate values of \( N \) nevertheless manage to harbor intermediate levels of variation for synonymous changes and to avoid fixing the major synonymous codon or having codon usages solely determined by mutation pressures. All of this could not be possible under the slightly deleterious model if \( N \) changes by more than a factor of 3 up or down from the value \( 1/s \). This point is also stressed by the fact that genes on the fourth chromosome of Drosophila show clear signs of biased usage of synonymous codons despite the fact that the extremely low levels of polymorphism in this chromosome indicate that its local \( N \) should be reduced well beyond 10-fold, making the maintenance of such bias not possible. The \( s = 1/N \) assumption is thus clearly untenable, which does not necessarily imply that more realistic models will not allow nearly neutral dynamics to take place when genes are close, e.g., to an optimum codon usage pattern. Exciting new patterns of polymorphism and divergence will have to be mined in order to address this and many other important questions—an endeavor that will fundamentally bring the evolutionary and population genetical understanding of molecular diversity well beyond its current state.

**VIII. THE VALUE OF MOLECULAR DIVERSITY AND CONSERVATION BIOLOGY**

Diversity on Earth is endangered, and so is molecular diversity at both the polymorphism and the divergence levels. Much has been written about the value of the divergence component of diversity and about the need to preserve the biological information contained in adaptations evolved over millions of years in species and locally adapted gene pools all over the world. Conservation biologists are aware that the polymorphism component of genetic diversity may be important for the survival of a species and therefore try to preserve it. However, that they do it and the way in which they do it is important not only for evolutionary research but also for the other biological sciences. In fact, the polymorphism patterns of many species with large effective population sizes have been shaped during millions of generations by the action of very small selection intensities. Such patterns may take too long to recreate by expanding a population and allowing selection to act for a sufficient amount of time and/or due to effects too weak to study with standard laboratory techniques. The information in these patterns can indirectly guide researchers to subtle but important molecular biological, cytological, and physiological effects of mutations but will be lost if such populations disappear or their numbers are reduced drastically. Therefore, conservation biologists should also strive to conserve large “unendangered” populations.

I. The Nature of the Organism

II. Diversity in the Real World: A Precis of Current Organismal Diversity

III. Summary

---

GLOSSARY

entropy An expression or measurement of the energy available for use by a system, including living systems; often described as the extent to which the system tends toward a state of disorder or randomness.

extremophile An organism that requires, or grows optimally in, extreme environmental conditions; e.g., extremes of temperature, pressure, or acidity.

heterotroph Literally, feeder on others; an organism dependent upon organic material from an external source to provide carbon for growth.

organism The smallest entity of life that can function as a whole, distinct from others of the same type; a single living being.

photoautotroph An organism that uses inorganic material as a source of carbon for growth, and light as an energy source; e.g., plants.

---

ORGANISMS ARE THE SMALLEST functional wholes of life, entities that impose themselves on their surroundings and are causally affected by them. Organisms are localized in space and time, connected with their surroundings, including other organisms, through ecological and behavioral interactions and with their evolutionary past through genealogical inheritance. Composed of smaller parts, they are themselves parts of larger wholes, such as demes, populations, species, guilds, communities, and ecosystems. These diverse connections provide opportunities and challenges for any organism-focused efforts to understand, manage, and preserve biodiversity.

I. THE NATURE OF THE ORGANISM

A. The Basic Units of Selection

Long before the advent of modern evolutionary thinking in the nineteenth century, organisms were recognized as a primary focus of observation and explanation of biological systems. Darwin extended this tradition by reserving a central role for organisms and organismal diversity in his theory of evolution by natural selection. He believed that evolutionary change resulted from the interaction of two factors, which he called "the nature of the organism" and the "nature of the conditions." Of these two, Darwin (1872) proposed that the nature of the organism...
as far as we can judge, dissimilar conditions; and, on the other hand, dissimilar variations arise under conditions which appear to be nearly uniform.

(p. 32)

Darwin thought that organisms were historically and developmentally cohesive wholes, and therefore it was in the nature of the organism to produce offspring that were all highly similar (but not identical) to each other and to their parents and other ancestors. He also postulated that reproduction produced variation without regard for environmental conditions and therefore it was in the nature of the organism to produce these offspring in numbers far exceeding the resources available for their support. When this inherent overproduction produced variety in critical characters, natural selection would preserve the versions that were functionally superior in that particular environmental context (adaptations). Whenever an environment changes, those organisms that already had the adaptations necessary to survive would do so, whereas those lacking appropriate adaptations would not. Selection did not create the adaptations—it only determined which ones, if any, would be favored for survival. The production of organismal diversity thus required that organisms be at once autonomous from, and sensitive to, the environment. Darwin's perspective contrasted sharply with Lamarck's proposal that adaptation was an immediate and directed response by organisms to their surroundings. Lamarck also believed that the nature of the organism was important in the production of diversity, but only because all organisms have the same ability to change according to their needs. Therefore, whereas Darwin postulated that the nature of the organism included autonomous, self-regulating properties, Lamarck believed that the nature of the organism was to be directly and completely connected to the environment.

The distinction between Lamarckian adaptationism and Darwinian selectionism became increasingly blurred in the second half of the twentieth century as biologists focused more attention on parts of organisms and less on organisms as wholes. This reductionist movement, driven first by the successes of population genetics and later by the development of molecular methods, may have been an unconscious response to developmental biologists' discoveries of the complexities underlying the transition from DNA sequences to complete organisms—complexities that threatened to swamp simplistic theories based on the mantra of one gene—one trait—one selection vector. Whatever the reasons, losing the perspective on whole organisms led to a loss of Darwin's panoramic view of biological diversity. In the last quarter of the twentieth century there have been many efforts to reemphasize the nature of the organism in evolutionary biology (Brooks and Wiley, 1988; Brooks et al., 1989; Brooks and McLennan, 1990; Depew and Weber, 1995; Kamin, 1991; Kaufman, 1993; Lewontin, 1982, 1983; Maynard Smith and Szathmáry, 1995; Odling-Smee et al., 1996; Raff, 1996; Salt, 1993; Van de Vlijver et al., 1998). These perspectives reassert that orderliness and organization in biological systems result from the interaction of selection processes with the inherent nature of the organism.

B. Organisms as Energy Flow Systems

Lotka (1913, 1925) was among the first twentieth-century authors to discuss biological systems, including organisms, in terms of energy flows and energy partitioning. He recognized that biological systems persist in space and time by transforming energy from one state to another in ways that generate and maintain organized structure. Maurer and Brooks (1991) recognized two classes of such energy transformations. Heat-generating transformations involve a net loss of energy from the system, usually in the form of heat. Conservative transformations involve changing free energy into stored states (e.g., structure). Because all conservative transformations in biological systems are coupled with heat-generating transformations, there is a heavy energetic cost to maintaining structure. Lotka (1913) suggested that the interplay between flow and partitioning of energy in biological systems acts to slow the rate at which energy stored by conservative transformations is degraded by heat-generating transformations.

The development of nonequilibrium thermodynamics in the past 50 years (Prigogine and Stéphane, 1946; Prigogine, 1980) has allowed us to generalize Lotka's view of the nature of the organism. Living systems are nonequilibrium thermodynamic systems; they exchange matter and energy irreversibly with their surroundings and they maintain themselves in far from equilibrium conditions. The basic features of nonequilibrium systems can be summarized heuristically as

\[
d\dot{S} = dS + dS, \quad dS > 0
\]

Total entropy changes \((dS)\) can be subdivided into two components: \(dS\), which measures exchanges between the system and its surroundings (changes in the surroundings), and \(dS\), which measures production by irreversible processes internal to the system (changes within the system). We can also call this heuristic equation the "cost of living" for organisms because all organi-
isms must take in high-grade energy and matter and dissipate lower grade energy to their surroundings in order to survive. Energy degraded in the uptake of raw materials from the surroundings into the system is dissipated into the surroundings \( dS \). These exchanges are accompanied by a great deal of waste; hence, \( dS \) is very large compared with \( dS \). Nonetheless, it is in the manifestations of internal production that we perceive organismal diversity.

Internal production \( dS \) includes (i) dissipation from the system, called the external dissipation function \( \gamma_e \), or heat-generating transformations). Heat-generating processes occur when energy and entropy flow in opposite directions, with entropy production tending to move the system toward disordered states; and (ii) dissipation within the system, called the bound dissipation function \( \gamma_b \), or conservative transformations. Conservative transformations are characterized by energy and entropy flowing in the same direction, with entropy production being retained within the system and tending to move the system towards more structured states. In biological systems, \( \gamma_b \) can be further subdivided into allocations for accumulating biomass \( \gamma_b^2 \) and allocations for accumulating genealogical information \( \gamma_b^3 \). Heuristically (Brooks and Wiley, 1988),

\[
dS = \gamma_e + \gamma_b^2 + \gamma_b^3
\]

Organisms thus have a dualistic nature. As open thermodynamic systems, they must simultaneously interact with their surroundings and perform critical functions internally. They maintain themselves in a viable state by exchanging matter and energy irreversibly with their surroundings, taking in relatively high-grade energy and using it to perform useful work within themselves. This requires sensing of, and causal engagement with, the surroundings mediated by a physical distinction ("phase separation", Prigogine, 1980) between the organism and its surroundings. That is, there must be an "inside" and an "outside" of the organism, delineated by a physical boundary. For all organisms, this boundary is provided by cell membranes, which are simultaneously physical barriers between the inside and outside of the organism and highly selective mechanisms for modulating the exchange of matter and energy between the organism and its surroundings. For multicellular organisms, this barrier is a complex of cell membranes.

C. Organisms as Information Systems

Elucidation of the genetic code made it possible to begin thinking of organisms as information systems. Information systems consist of a source of signals, a channel through which the signals are transmitted, and a receiver to translate the portion of the signals that made it through the channel into information. Gauvin (1972) argued that the genetic system is the source, reproduction and ontogeny are the channel, and the environment is the receiver. Genetic possibilities thus become phenotypic signals as a result of reproduction and ontogeny and become meaningful biological information as a result of causal interactions between the phenotype and the environment. Brooks and McLennan (1990) noted, however, that the environment is not a receiver in a physical sense because its only causal interaction with biological information is the possible elimination of some of it; it does not measure or interpret the information. Rather, the environment acts as interference in the channel, or as a "delete button" monitoring "incoming messages," eliminating relatively less fit organisms.

If biological information is a material part of biological systems, however, it is possible for biological systems to be their own sources and receivers. Current standard evolutionary theory stresses external causality for orderliness in biological systems, so the receiver has been construed as part of the surroundings, i.e., localized in space. Although it is true that biological systems are localized in space, they are also localized in time. In other words, the receiver can be a "time" (Brooks and McLennan, 1990). The source is a genetic system at time \( t_0 \), the channel is reproduction and ontogeny, and the receiver is the same genetic system at any given time \( t_1 \); thus, the receiver is temporally distinct from the source. If an information source precedes its receiver in time, it can produce the system that acts as receiver, and that system can then become a source. This perspective has been used by information theorists designing self-correcting computer programs, which can enhance their own abilities to store and transmit information efficiently. The same holds true for biological systems: DNA has significant self-repair capabilities.

Biological systems are physical information systems, a type of nonequilibrium thermodynamic system, open to exchanges of matter and energy but maintaining a closed information system internally which functions to reproduce the system—to perpetuate lineages through time. They are able to impose themselves and their functions on their surroundings and thus are self-stabilizing and self-organizing. They produce organized complexity cheaply \( dS \) is small compared to \( dS \), and the portion of \( dS \) allocated for the information system is small, in part because a small number of chemical templates are used to generate many organisms), variability (because even chemical templates are subject to
the statistical mechanical vagaries of the second law of thermodynamics), and functionally (because organisms must exchange matter and energy with their surroundings in order to maintain themselves), but without regard for details of the surroundings (because the information system is embodied in relatively autonomous internal chemical production, $dS$, of the system). As the source and receiver of organized information, they can be the embodiment of the organizing principles for that information. Biological systems thus transmit information through, not to, their surroundings. This supports Darwin's view that it is the (autonomous) nature of the organism that creates the necessary conditions for selection processes, especially natural (environmental) and sexual selection, to occur.

Treating biological systems as physical information systems provides a causal basis for the origin of selection processes consistent with their well-documented causal consequences. Selection processes originate as a result of the necessity that biological systems obtain matter and energy from their surroundings coupled with the relative autonomy of their information systems, which permits production of organisms regardless of the details of their surroundings. Without the constraints provided by this autonomy, there would be no selection; simultaneously, however, constraints provide systems with macroscopic properties that limit the ways in which and the extent to which the system will respond to selection. This means that biological systems should have their own macroscopic, or macroevolutionary, properties that are not reducible to microscopic dynamics. Some of the most important implications of reemphasizing the nature of the organism in the context of thinking of evolution as an informational process involve the manner in which evolutionary theory views major events in the history of life (Maynard Smith and Szathmary, 1995).

D. Putting It All Together

Biological systems, beginning with organisms, are functional wholes with respect to the way they engage their surroundings and with respect to their internal organization. A major component of internal organization is functional integration through the interdependence of parts, and this is most evident in the dynamics of ontogeny (Salthe, 1993; Raff, 1996) and in physiological processes. Evolutionary changes in biological systems do not occur at all at the same time; thus, when such changes occur, only part of the system changes. All changes, whether point mutations on a chromosome, genomic doubling, or alteration of part of a complex mating ritual, must integrate with the rest of the system, which has not changed, in such a way that viable organisms result. The functional necessity of developmental integration creates stability domains within bioinformational phase space (Brooks and Wilke, 1988; Kauffman, 1993; Niklas, 1999). Orderliness and organization in biological systems result from the interaction of selection processes with three aspects of the nature of the organism: (i) historical uniqueness, (ii) cohesive properties, and (iii) hierarchical organization.

Historical uniqueness manifests itself in historical contingency but, more importantly, in temporal irreversibility. Important organismal processes such as reproduction, development, aging, and death are inherently irreversible. Spontaneous irreversible behavior of this sort always involves growth and increasing complexity, and physical manifestations of at least some of the systems' history (Schnick and Wimsatt, 1988).

Cohesive properties range from membrane-bound nucleic acids to cell-cell adhesion and recognition, sexual reproduction and specific mate recognition systems, and common history of inheritance. Cohesion is especially important to evolutionary explanations; it is the "glue" of functional integration and hierarchical organization that are so characteristic of biological systems (Wake and Roth, 1989). Many biological processes that demonstrate irreversible behavior manifest such changes as a result of interactions among cohesive factors.

Hierarchical organization plays an important role in organismal diversity. Hierarchies provide stability, reinforce boundaries between organisms and their surroundings, allow increasing amounts of complexity without losing organizational coherence, and provide a way in which causation and control can be tied together (Salthe, 1993). Eldredge and Salt (1984; see also Eldredge, 1985, 1986; Salt, 1993) emphasized two major forms of hierarchically organized biological structure. The ecological hierarchy (interactors of Hull, 1988) is manifested by patterns of energy flow in ecosystems, and the genealogical hierarchy (replicators of Hull, 1988) is manifested by patterns of ancestral relationships among organisms and species. Environmental and genealogical phenomena are good starting points for investigating hierarchical interactions because they are intimately connected in biology. Prebiotic environmental conditions established the boundary conditions within which life could originate. Conversely, genealogical processes that characterize life are autonomous enough from environmental conditions to be capable of overrunning available resources and of changing the environmental conditions substantially. The longer life
exists on this planet, the more it shapes the environment of the planet. Today, much of the environment relevant to biological systems consists of other organisms (Maynard Smith, 1976; Brooks and Wiley, 1988). Organisms imposing themselves on their environments (creating niches) contributes greatly to the far from equilibrium nature of the environment in which evolution occurs (Odling-Schmee et al., 1996).

The intimate relationship between the two hierarchies can be illustrated with a sports metaphor: The ecological hierarchy establishes the dimensions of the playing field, whereas the genealogical hierarchy establishes the rules of the game being played. In other words, biological systems obey rules of self-organization transmitted genealogically (historically) and played out within environmentally defined boundaries. To complicate matters, however, the self-organizing rules of the game by which living systems evolve can produce changes in the dimensions of the playing field. To extend the metaphor, the game may redefine the dimensions of the playing field and may be subsequently constrained by those self-imposed changes. For example, the evolution of photosynthetic prokaryotes from anaerobic ancestors resulted in increased oxygen content in the atmosphere. This increase then altered the diversity and changed the distribution of anaerobic organisms, limiting them to relatively rare environments and paving the way for the evolution of a new array of species. Now that we have a consistent view on the nature of the organism in a physical sense that also accounts for their Darwinian nature, we can discuss observed organismal diversity.

II. DIVERSITY IN THE REAL WORLD:
A PRECIS OF CURRENT ORGANISMAL DIVERSITY

Organismal diversity is evolved diversity. This means that no matter how distantly related two organisms are, they still share at least some features in common, such as cell membranes made of lipid-bilayers and a common genetic code, linking them to a single phylogeny of life on this planet. Highlights of organismal diversity can thus be best recounted in a precis of organismal diversification—phylogeny. However, phylogeny is not a linear historical timeline. It is a hierarchically branching pattern of diversification and spread, producing organisms that are historically unique mosaics of ancient and recent traits, both functional and structural. Therefore, it is not possible to give even a precis of organismal diversity without twists and turns. The perspective on the major transitions in evolution presented by Maynard Smith and Szathmary (1995), however, provides some consistent reference points. Maynard Smith and Szathmary suggested that the major transitions in evolution occurred whenever life functions were compartmentalized and modularized in such a way that the reproductive flow of biological information was enhanced. This can occur either by enhancing the survivorship of organisms in particular environments, thus increasing the likelihood that they will reproduce, or by enhancing the mechanisms by which information is stored and transmitted, regardless of the particular environment in which it evolves. Maynard Smith and Szathmary highlighted what they considered to be the nine most important evolutionary transitions, all of which were examples of enhanced efficiency of information storage and transmission.

One observation that is relevant is that the smallest and the largest organisms known to have existed in the past exist today. Members of Thermoplasma are thermophilic and acidophilic prokaryotes living in coal deposits that possess only 1100 kilobase pairs of nucleotides in their genomes, whereas blue whales are oceanic monsters outstripping even the largest of the dinosaurs.

The oldest lineages of organisms on the planet are various prokaryotes, including bacteria and archaeans. These organisms are single celled, lack organelles or membrane-bound genomes, and exhibit only asexual or simple parasexual reproduction. Their cells form only rods, spherites, or spirals, and yet they have inhabited this planet continuously for almost 3 billion years and represent by far the largest number of differentiated lineages on the planet today, including the largest number of unnamed taxa. Representatives of the prokaryotes include chemoheterotrophs (thought to have been the lifestyle adopted by the first living things), chemoheterotrophs, phototrophic, and photoautotrophs. Photoautotrophic prokaryotes, primarily Cyanobacteria, were the first to demonstrate that organisms could change the environment of the planet, substantially affecting standing biodiversity. They did this by releasing large amounts of molecular oxygen into a reducing atmosphere, changing it in such a way that most prokaryotes became extinct or restricted to marginal habitats. This release of oxygen, as well as associated nitrogen fixation, by prokaryotic photoautotrophs created the conditions necessary for other life forms to evolve, so it is safe to say that prokaryote evolution played a major role in setting the stage within which all subsequent biological diversification occurred. Prokaryotes today include the so-called Archaea, or extremophiles,
which may represent a collection of distantly related remnants of the diversity affected so much by the evolution of those photoautotrophs. Among the extremophiles are members of the halophilic Halobacterium, which grow best at pH 11.5, and the acidophilic Sulfolobus, growing best at pH 2 or 3 but able to survive at pH 0.9. There are methanogens, producing most of the planet's methane, including a host of symbionts living in the rumens of cattle and their relatives in which they produce digestible carbohydrates for their hosts as well as methane. Another methanogen, Methanopyrus, which lives near ocean-bottom thermal vents, grows optimally at 98°C but is able to survive at 110°C and "dies of cold" at 84°C. Sulfolobus is also a hyperthermophile, living optimally at 70–75°C and dying at temperatures lower than 55°C. The extreme thermophile Thermus aquaticus, isolated from hot springs in Yellowstone National Park, was the original source of high-temperature DNA polymerase, the enzyme used to catalyze the polymerase chain reaction (PCR) technology that has become indispensable to molecular biology. Most other prokaryotes are bacteria, which include some of mankind's most valued and most loathed organisms. Bacteria living in our digestive tracts are essential for proper nutrition, and Escherichia coli is the workhorse of molecular biology and biotechnology, including the pharmaceutical industry. On the other hand, diseases such as syphilis, anthrax, diphtheria, tuberculosis, smallpox, tetanus, cholera, and plague and a variety of agents of food poisoning, including Salmonella and botulism, are all caused by bacteria. These same disease-causing prokaryotes have also shown a tremendous degree of adaptability in the face of substantial human efforts to eradicate them.

From within this great prokaryotic diversity evolved the first eukaryotes. Most species of eukaryotes, including the oldest surviving lineages, comprise single-celled organisms differing from prokaryotes by well-organized compartmentalization of functions within the cell. Cell energetics are handled by organelles called mitochondria and chloroplasts, which are thought to have originated as endosymbiotic prokaryotes. Digestion and excretion are handled by specialized vesicles within the cell that facilitate the movement of matter and energy in and out of the cell. Synthesis of amino acid building blocks for structural components takes place in specialized organelles called ribosomes. Finally, the storage, production, and transmission of information are compartmentalized inside a membrane-bound nucleus. Powered locomotion, first evolved by prokaryotes in a rudimentary manner, becomes highly effective in unicellular eukaryotes as a result of sophisticated cytoskeletal integration.

Most of the heterotrophic unicellular eukaryotes are grouped together in a nonmonophyletic collection of lineages called the Protista. Within this evolutionarily heterogeneous and diverse collection of lineages are the origins of the first sophisticated sexuality as well as alternation of sexual and asexual generations (diverse examples are found in ciliates, apicomplexans such as malaria, and various algae), the first sophisticated modifications of the cell membrane in ways that modulate organism–environment interactions (diatoms produce complex and beautifully sculpted exoskeletons), and the beginnings of true multi-cellularity, manifested by colonial aggregations of unicells that exhibit some degree of functional differentiation, such as the fruiting bodies of slime molds.

The protists are major underpinnings of the heterotrophic portions of the biosphere. Within the heterotrophic realm, protists represent saprophages and detritivores, predators, and a variety of symbionts, ranging from commensal ciliates living in the tests of sea urchins and the rectums of frogs to mutualist flagellates living in termite guts, providing digestible carbohydrates for the insect hosts in exchange for their own food and a safe haven, and parasites of global socioeconomic significance, including the causal agents of amebic dysentery, malaria, giardiasis, African sleeping sickness, Leishmaniasis, and Chaga's disease. Most show enhanced reproductive output and complex life cycles, but Giardia and Entamoeba show some secondary losses of structures.

The photoautotrophic protists, generally called Algae, comprise four distinct lineages: dinoflagellates, red algae, diatoms, and the green algae. The dinoflagellates are best known as the causal agents of red tide. Massive blooms of certain dinoflagellates produce large amounts of waste products that act as nerve toxins capable of killing large numbers of fish or of concentrating in shellfish and killing those who eat them. Red algae also include some basal species that are parasitic in more derived members of the same clades. Diatoms are ubiquitous phytoplankton that represent the primary source of photosynthesis (and oxygen production) in the ocean, although many are freshwater inhabitants. They are characterized by having bipartite siliceous shells (tests), exhibiting species-specific forms and beautiful surface sculpting. Because they are siliceous, these tests are highly resistant to decomposition. As a result, fossil deposits of diatoms are excellent indicators of past environmental conditions. Large deposits produce "diatomaceous earth," which has many industrial uses including insulation, filtration, and metal polishing. Diatomaceous earth has also been proposed as a "non-polluting" insecticide. Spreading diatomaceous earth on
fields may well clog the tracheae of pest insects but will also clog the tracheae of beneficial insects and may also affect the breathing structures of other animals, including those humans who apply it or work in fields on which it has been applied.

True multicellular lineages appear to have evolved four times within the protists: the brown algae and plants, which are photoautotrophs, and the fungi and animals, which are heterotrophs. According to Maynard Smith and Szathmary, multicellularity represents an advance over unicellularity because in multicellular organisms the partitioning of functions can occur at the level of entire cells, tissues, organs, or organ systems rather than having to take place within each cell. Complex reproductive systems can evolve because multicellular organisms can produce gametes without having to become gametes. Given the large numbers of unicellular eukaryote lineages and the small number of multicellular eukaryote lineages, we conclude that this is difficult to achieve, despite the evolutionary payoffs. Perhaps this is because it is difficult to coordinate a population of cells. There are no multicellular prokaryotes (there are bacteria that form strings, strands, and mats, but these are simply aggregations of individual organisms), perhaps because prokaryotes show no functional partitioning at the cellular level. If so, true multicellularity could only have arisen after unicellular eukaryotes evolved. In a complementary vein, there is only a single known example of secondary loss of the multicellular state; this occurred in the Microsporida, a group of obligate parasites of fishes and annelids which were thought to be an apicomplexan protist group until it was shown that they are actually highly modified cnidarians.

Each of the four cases of true multicellularity represents a very different evolutionary path. The least successful of these are the brown algae, sister group of the diatoms. Up to 60 m long in the case of Macrocytis, brown algae can be found on ocean shores with pounding surf, in relatively quiet near-shore meadows, or floating in the open ocean. The Sargasso Sea, for example, is an enormous mass of floating Sargassum. Although relatively species poor, brown algae can be abundant. They exhibit differentiated tissues and even organs, including holdfasts and filaments, which are analogs of roots and leaves that provide homes to a diverse array of animal life. Some have gas-filled bladders which may contain up to 5% carbon monoxide—enough to kill a human. Cellular cohesion in brown algae is provided by alginate acid in the cell walls. This is a gummy polymer of sugar acids that cement cells and filaments together and provides the glue for the holdfasts. Alginate acid is also an important commercial emulsifier in ice cream, cosmetics, and other products. Larger pieces of brown algae, especially some kelp species, are considered delicious and healthy food sources for humans.

The remaining three groups of multicellular organisms are relatively closely related to each other, albeit they diverged a very long time ago, and to two groups of protists—the photoautotrophic green algae and the heterotrophic choanozoa.

The second group of multicellular photoautotrophs are the plants, sister group of the green algae, or at least of some green algae. Unlike the brown algae, which originated in the sea and have remained there throughout their evolutionary history, plants are the descendants of an aquatic lineage that invaded and diversified on land. Two closely related living relatives of the true plants are Volvox and Micrasterias (sea lettuce), which form aggregates of single-celled organisms showing some degree of functional differentiation, including the production of large stationary eggs, which are highly differentiated from the very small, flagellated, and highly mobile male gametes, a condition also found in true plants. Cellular cohesion in true plants is provided by plasmodesmata, which are cytoplasmic strands connecting adjacent cells. Many plants exhibit a high degree of adaptability or permissiveness with respect to genome-level evolutionary modifications. Polyploidization is common among many groups, including both autopolyploidization and allopolyploidization as a result of interspecific hybridization.

The land represented an excellent substrate for photoautotrophs because there is more consistent sunlight on land than in the sea, where sunlight of sufficient quality for photosynthesis to occur does not penetrate deeper than approximately 50 m. However, being on land also posed problems, one of which was structural: Air provides little support compared to water. In the absence of inherent structural support, plants could only sprawl on the land—they could never rise above it. Cell walls made rigid by cellulose, a carbohydrate, provided the necessary structural support. Subsequent evolution of vascular tissue in a moss-like ancestor and then a sophisticated tubular transport system (tracheids) in the ancestor of the sister group of the mosses (those plants called, not surprisingly, Tracheophytes) enabled water and nutrients to be transported against gravity to considerable heights. Rigid cell walls and the tracheid system provided opportunities for tremendous vertical growth, represented by the convergent evolution of tree forms in many groups (including giants up to 110 m tall) and a tremendous flow rate of water and nutrients. A single maple tree only 15 m tall may support more than 175,000 leaves with a total surface area of more than 675 m², transporting up to 220 liters of
water per hour from the soil throughout the tree and eventually into the atmosphere through evaporation from the leaves.

Terrestrial life that is truly independent of aquatic environments must also be associated with suitable reproductive modes. When ancestral plants moved onto land, they brought with them the large stationary eggs characteristic of their closest relatives. In all land plants, when these eggs are fertilized, the resulting embryos are sporophytes contained within a protective covering produced by the parent. Those ancestral plants also brought with them aquatic flagellated sperm, maintaining a dependency on aquatic surroundings, at least for reproduction. Only when nonaquatic male gametes evolved in early angiosperms did land plants become completely terrestrial.

Once firmly established on land, major events in plant diversification were associated with increasing compartmentalization and modularization of the organism, all integrated and coordinated chemically and without a centralized nervous system. They elaborated functionally differentiated nonreproductive body parts, especially roots and leaves, that became specialized habitat for other terrestrial dwellers, creating many novel opportunities for diversification by these others and coevolutionary feedback that affected their own evolution as well. This included the evolution of parasitic plants such as Indian pipe, which has lost its chloroplasts and depends on the host plant for photosynthesis. Their root systems helped plants modify the soil in ways that enhanced the lives of the plants themselves but also affected the lives of plants and other types of organisms living in the soil. Some plants today produce toxins in their roots that diffuse in the soil, inhibiting the growth of other plants. Others, including common garden plants such as marigolds, secrete substances from their roots that deter plant-consuming soil nematodes and thus can be planted as a nonpolluting nematicide border in gardens. Aboveground vertical growth in tracheophytes led to a proliferation of types of habitats—plants, shrubs, bushes, vines, and trees. This vertical structuring allowed complex communities of plants to form, within which the various plants created their own ecological interactions with other plants by shading each other. Plants also differ in the relative amount of biomass allocated to below- and aboveground structure. This led to complex ecological interactions between root systems of different plants. In the tropics, for example, most plant biomass is aboveground, whereas in temperate areas in which there is more humus in the soil, a much larger proportion is belowground. In fact, a given plant may participate simultaneously in one set of aboveground and another set of belowground ecological interactions, just with other plants, depending on what species the plant belongs to and where it happens to be growing.

Plant organismal diversity is also associated with major modifications of the reproductive system, each of which has many variations. Primary among these was the evolution of seeds, which are embryos protected by a covering of nutrient tissue provided by the parent. These multicellular protective coats, containing cellular contributions from as many as three generations, are a source of protection and nutrition for the embryos which may allow them to withstand substantial periods of environmental harshness and still be capable of germinating and producing a plant. The earliest seed plants produced seeds exposed directly to the environment, called gymnosperms (naked seeds). Angiosperms (hidden seeds) evolved when the ovaries, containing the seeds, expanded into fruits, hiding the seeds and providing more protection. The evolution of double fertilization at more or less the same point in time, producing triploid endosperm, provided even more nutrition for the embryo. Angiosperm diversification produced some amazing organisms. The seeds of some plants need to be burned by forest fires in order to germinate, and others must pass through the intestinal tracts of herbivorous vertebrates before they germinate. Plant seeds today exhibit an immense array of structural modifications that enhance their dispersal from the parental plant. Those that pass through the intestinal tracts of vertebrate herbivores may be dispersed for many kilometers from their parental plants by the herbivore. Other seed modifications take advantage of wind—from the fluffy dandelions to the robust winged samaras of maples. Another major reproductive innovation was the evolution of flowers, which are specialized and self-contained reproductive modules. Flowers represented an enormous potential for reproductive cohesion and diversification.

The evolution of plants was followed closely by the evolution of herbivores, especially among the nematodes and insects. This in turn was followed by the evolution of a variety of antiherbivore adaptations. Defenses against herbivory include both diminution and elaboration of the part of the plant being eaten, the evolution of surface features such as thorns, and storage of toxic metabolic by-products in tissues that are targets of herbivory. Likewise, the diversification of flowering parts is also associated strongly with the diversification of particular groups of animal pollinators, again most notably insects. In fact, it appears that the evolutionary diversification of flowering plants and of phytophagous
insects has been facilitated by their close ecological associations.

Plants exist in many seemingly inhospitable habitats, particularly desert and boreal regions, where the evolution of resistant seeds as well as specialized reproductive, root, and stem and leaf systems allow them to survive and thrive. Cacti and other succulents represent convergent evolution of water-retaining and evaporation-resistant body forms that can survive in desert conditions. Many plants are able to flourish in nearly marine salinity conditions, although none is truly marine. Mangroves, for example, are able to excrete excess salt from the water they absorb in the tropical coastal estuaries in which they live. Plants also thrive in seasonally fluctuating environments. This is helped by the evolution of resistant seeds but is also enhanced by the ability to synchronize growth and reproduction with permissive times of the year. For example, the ability to shed leaves deciduously apparently arose as an adaptive response to seasonally dry climates but today functions in seasonally cold climates as well.

Tapping an almost unlimited energy source (sunlight), coupled with their sophisticated means of compartmentalization, has made plants extremely important to humans and to the biosphere. Terrestrial plants improve air quality by fixing carbon. Some also help improve the ability of soils to sustain life by fixing nitrogen mediated through mutualistic relationships with root-dwelling bacteria; the best known of these mutualists produce the root nodules called peanuts. Plants that have adopted life in freshwater habitats are often quite sensitive to changes in water quality and are thus useful as indicators of pollution. Those having extensive aquatic root systems may also be excellent biofiltration systems; water hyacinths, for example, can actually improve water quality. The cultivation of plants is thought to have been a major event in human evolution. Ironically, the cultivated production of large quantities of edible plant biomass is thought to have provided the conditions for the growth of human population and technology that now threaten our existence by threatening the biosphere. Different plants allocate substantial amounts of nutrients into root systems, especially tuberous ones, into stems and leaves, and into reproductive structures such as nuts, seeds, and fruits. Virtually any part of a plant may be highly edible for humans or their domestic animals. Simultaneously, substances functioning to deter herbivory or competition from other plants may also serve as sources of useful materials for humans, ranging from spices to pharmaceuticals. The American yew tree sequesters a compound called taxol, which has significant effects on certain forms of cancer.

a close relative, the European yew, produces a similar compound called taxotere, which also has anticancer properties.

Fungi represent one of the two major groups of multicellular heterotrophs. Among living groups, fungi are apparently the sister group of choanoflagellates and animals. Cellular cohesion in fungi is provided mostly by default: The vegetative body of a fungus, called a mycelium, comprises many hyphae, which are filamentous multicellular extensions maintaining cohesion among the cells by forming only incomplete cellular divisions, or septa, between them.

To many people, the presence of fungi indicates that something has gone wrong—one’s basement is too damp or one’s bread is too old. To others, fungi are something quite different: They are the major recyclers and decomposers of the biosphere, found most commonly in association with the refuse of the biosphere, including that of our own civilization. This is because most fungi are very adaptable saprobes, highly tolerant of great ranges in temperature and osmotic, especially hyperosmotic, conditions. A considerable number of fungi are parasitic and a few are even predators, attacking small animals such as soil nematodes. Fungi are very flexible reproductively, reproducing sexually or sexually with mating types not distinguishable as male or female and exhibiting an enormous diversity of variations on the general eukaryote theme of alternation of generations. Fungi are the primary source of cellulose and lignin breakdown in the environment. These features make them excellent agents for bioremediation. They can become established in highly degraded habitats and actually improve them, creating conditions which can support yet more life. Tropical forest soils, for example, lack much humus but have enormous mats of fungal hyphae forming mycorrhizal mutualisms on and in plant root systems, which maintain vital nutrients and structural cohesion in the small amount of soil that is present. Fossil evidence suggests that mycorrhizal associations are at least 300 million years old.

There are four major groups of fungi. The Chytridomycota, or water molds, are thought to be the sister group of the rest of the fungi. Chytrids have been implicated in recent massive die-offs of amphibians living above 1000 m elevation throughout the world. Many chytrids are known to be parasitic, with some exhibiting complex life cycles involving two different hosts. A few have been found that are predators of nematodes. Members of Arthrobotrys, Dactilaria, and Dactyella produce three-celled loops that entrap nematodes as they wind their way through the soil; once trapped, the
nematode cuticle is invaded by hyphae and ingested. The fungi most commonly known as "molds" are members of the Zygomycota. These fungi are also arguably the basis of the modern pharmaceutical industry—the mold that tells you your bread is too old is likely Penicillium, the original source of the world's first broad-spectrum antibiotic, penicillin. Two other members of the genus, P. camemberti and P. roqueforti, are required to produce fine cheeses. Some members of Aspergillus are essential to the production of soy sauce and sake, whereas others can cover edible products such as peanuts with carcinogenic aflatoxins. Probably the best known and respected fungi are members of the Basidiomycota. This group includes the edible fungi, called mushrooms, morels, or truffles, in ascending price. This group also includes rusts and smuts, which can cause serious diseases in agricultural plants. Basidiomycetes are also a major source of legal and illegal pharmaceuticals and some of history's most infamous deadly toxins. The sister group of the basidiomycetes are the members of the Ascomycota, which comprise the yeasts and sac fungi. Without members of this group, we would have no bread, yogurt, or many alcoholic beverages, including wine and beer.

On their own, fungi are ubiquitous and numerous throughout the world. In addition, some fungi form mutualistic associations with algae, called lichens, which are perhaps the champion extremophiles of the multicellular world. Extremes of heat and cold and dry and wet do not seem to deter lichens, who often flaunt their hardiness by living on rocks, slowly but inexorably digesting them into dust.

The second group of multicellular heterotrophic eukaryotes are the Metazoa, or true animals. Metazoa are the sister group of the choanoflagellates. This group of multicellular organisms maintains cellular cohesion by means of extracellular matrices of cell-adhesion proteins. Unlike plants, which invaded the land early and diversified there, most animal diversification occurred in the ocean, and various groups have invaded freshwater and terrestrial habitats convergently. Even today, most metazoan organismal diversity is in the sea. A great deal is known about many metazoans, probably because many of them are large enough to be seen with the naked eye and active enough to engage visually oriented organisms such as ourselves. Most metazoans, however, are microscopic. Highly complex and sophisticated adult organisms, such as some rotifers, may be as small as 50 μm.

The array of metazoan body plans provides clear evidence of modularization and compartmentalization. Metazoan bodies range from aggregates of specialized cells in sponges and placozoans to defined body forms composed of specialized tissues in cnidarians and ctenophores, with organ-level organization beginning with platyhelminthes, and complex organ systems in the majority of the other metazoans. Body cavities emerged very early in metazoan evolution as effective ways of physically compartmentalizing organ-level modules and laid the evolutionary groundwork for specialized compartments within body cavities, called segments, metamers, and tagmata. Metazoan bodies may be asymmetrical as in sponges, radially symmetrical as in cnidarians, bilaterally symmetrical as in the majority of metazoans, or even biradially symmetrical as in ctenophores and echinoderms. Developmental patterns among metazoans tend to be highly conserved within major groups, although secondary loss of structures is not uncommon: the platyhelminthes appear to be descended from an ancestor that lost its body cavity, and a large group of parasitic platyhelminthes, dominated by the true tapeworms, has secondarily lost its digestive tract as well.

Many metazoans are conspicuous because they tend to move around a lot. Modes of locomotion are varied, but most are variations on swimming, creeping, or crawling. Sophisticated locomotion in metazoans is highly correlated with enhanced cephalization and neural integration. Cephalopod mollusks have water-jet propulsion provided by specialized siphons. Complex appendages for swimming, walking, and running evolved in the arthropods and the chordates. It is within these two groups that organisms capable of true powered flight emerged.

All metazoans are heterotrophs, but they exhibit the entire range of heterotrophic functions—they are saprobes, detritivores, filter and suspension feeders, predators, herbivores, commensals, mutualists, parasites, and parasites. Herbivory is uncommon among marine metazoans but is a major attribute of the structure of terrestrial ecosystems. Modern herbivory diversity is concentrated in the insects, the annelid vertebrates, and the nematodes. Interestingly, no metazoans ever evolved the ability to digest cellulose. Thus, many metazoan herbivores dine on plant cells and tissues that contain nutrients in a form other than cellulose. Those that actually gain nutritional benefit from cellulose are hosts to a variety of prokaryotic and eukaryotic microbes which possess the enzymes necessary to break cellulose down into less complex carbohydrates, which can be absorbed by the metazoan host. Although this form of herbivory seems to be very successful when it evolves, it does not appear to have evolved often, presumably because it is difficult to acquire the proper
symbiotic microbes, provide a suitable home for them in the intestine, and provide a means of transmitting them to offspring.

Herbivory has a downside, however. As indicated previously, many plants allocate toxic compounds to the structures eaten by herbivores. The herbivores that have survived such evolutionary changes in their food have evolved ways of avoiding, sequestering, or detoxifying those substances. Metazoa not only graze on plants but also many graze on other metazoa. Parasitism has evolved in virtually every group of metazoa except the chordates. The phylum Acanthocephala is entirely parasitic, whereas the vast majority of phyla are parasites, including the well-known digeneans (trematodes or flukes) and eucestodes (tapeworms). Many nematodes and arthropods are also parasitic.

Reproductive modes are diversified in metazoa. Most metazoan organisms are either males or females, although hermaphroditism is not uncommon in members of some of the oldest lineages. Gonads may be transient specialized cells or tissues or permanent organs and organ systems. Reflecting their ancient origins and diversification in the ocean, fertilization is pleisomorphic in most groups. Internal fertilization, in which the female provides the aqueous medium within which the sperm can swim to the ova, has evolved multiple times. The ancient eukaryotic theme of alternation of generations is carried forward into metazoan evolution, although it drops out in several lineages convergently. In many cases, the asexual and sexual portions of the life cycle are ecologically partitioned; in most cnidarians these stages are characterized by distinct medusa and polyp forms which have distinct ecologies. However, even for metazoa that do not exhibit alternation of generations, it is common for the larvae and adults to have very different life-styles. Most larval frogs, for example, are herbivores, whereas virtually all adults are insectivores. Among ecdysozoans (nematodes, rotifers, tardigrades, kynorhynchs, gastrotrichs, acanthocephalans, and arthropods), haplodiploidy is a common theme, setting the stage for extreme sexual size dimorphisms and asymmetrical sex ratios biased heavily toward females. Many metazoa are parthenogenetic, forming unisexual female lineages. In some cases, these lineages are entirely self-sustaining, whereas in others, such as the gynogenetic poecilid fish called the Amazon molly, sperm from males of a parental species are required to trigger embryogenesis, even though no genetic information from the sperm is incorporated into the embryo.

Another major theme of metazoan organismal diver-
sto is temporal synchronization of reproductive cycles. Perhaps the most extreme case is that of the tropical Pacific polychaete called the Palolo worm, in which the entire species reproduces in a single night each year. A more familiar example is that of anadromous salmonid fishes, in which adults return to their natal streams from the ocean once a year, reproduce, and die. In herbivorous insects reproductive synchronization is tied to cycles of growth and reproduction in the different plants they eat.

One of the most arresting features of animals is complex behavior, especially with respect to reproduction. This can be manifested in sophisticated interactions among males, among females, between males and females, in parental care, or even in complex combinations of all possibilities. Complex mating rituals have been documented in tardigrades, in which males are known to apply ritualized Stokes to females to encourage them to reproduce. Some leeches are known to carry their offspring on their abdomens for a period of time after birth. Mollusks (especially cephalopods), arthropods (especially insects), and chordates (especially vertebrates) are the best examples of sophisticated behaviors among metazoa. All three groups have evolved complex control and sensory integration involving neurochemical systems and strong cephalization.

One outcome of integrated and sophisticated behaviors is sociality. Maynard Smith and Szathmary (1995) designated the evolution of social systems as one of the nine major transitions in biological evolution. Social systems permit functional compartmentalization at the level of different organisms within a social group. This level of modularization and compartmentalization is best seen in the social insects, notably bees, ants, and termites, whose colonies function very much like superorganisms. The fundamental feature of these societies is genetically stereotyped individual organisms, most of whom are sterile or sexually inactivated female workers and soldiers (anals of somatic tissues) along with a few reproductively active males and females (the anals of reproductive organs). In bees and their relatives, colonies consist of many sexually inactivated females called workers and a smaller number of reproductively active males called drones, whose only function is to reproduce with a single queen, the reproductively active female. The other major group of social hymenopterans, ants, differs from bees and their relatives by having males that die shortly after reproducing with a queen and by exhibiting a tremendous range of morphologically distinct, functionally stereotyped workers and soldiers. Ant societies fascinated Darwin, especially their
propensities to wage war, make slaves, use tools, construct complex domiciles, and undertake agriculture, farming fungi and milking aphids for nutrients. The other major group of social insects are termites, whose colonies comprise a single queen and king who do all the reproducing. Sexual inactivation of offspring is maintained from one generation to another by pheromonal spread through trophallaxis, which is the mutual feeding of nymphs. Workers and soldiers produce pheromonal secretions whose proportions in the colony act to maintain suitable proportions of each type of individual in succeeding generations.

Some vertebrates, including many primates, also form social systems. These tend to be much less stereotyped than those of the insects, with more flexibility in roles in which individuals perform multiple tasks and all are reproductively competent. Members of vertebrate societies never lose their individuality. Actual reproductive patterns are constrained by behavioral dominance hierarchies, both male and female, that can be quite complex and can be based in large part on kinship. None, other than humans, come close to the frenetic and compartmentalized social activity seen in the colonies of social insects.

The predominant metazoan groups are the chordates, nematodes, arthropods, mollusks, annelids, and echinoderms. The most organically diverse group is the Ecdysozoa, which includes the nematodes and the arthropods. Within the arthropods, the insects alone represent more than 1 million named species, with many more remaining undescribed. Nematodes may be as species rich as insects, but only 15,000 nematodes species have been named. Feats of relative strength and tolerance of extreme environmental conditions are legendary among the insects; among the ecdysozoa, however, tardigrades may be the most amazing extremophiles of all, being capable of entering a state of cryptobiosis. Under desiccating conditions, tardigrades can experience a loss of total water content from 85% of their body weight to 3%. Furthermore, while in this state, tardigrades can withstand, sometimes for years, extreme temperatures, including cold to near absolute zero, ionizing radiation, almost total lack of oxygen, and up to 1000 atm of pressure. When moisture levels return to normal, normal life functions resume.

Although they represent a relatively small percentage of the total species on this planet, metazoans have a major impact on the biosphere. Early in the evolutionary history of metazoans, reef-building sponges and corals evolved, creating biogenic alterations in ocean current patterns and novel forms of habitat for additional life forms. Benthic metazoans make use of, and help maintain, the ocean bottom while annelids, nematodes, rotifers, and a variety of arthropods perform the same function for terrestrial soil systems. Many metazoans serve as habitat for other metazoans: in the life cycle of an individual tapeworm, a copepod, a mollusk, a ray-finned fish, and an elasmobranch may all serve as habitat. The many metazoans that are filter or suspension feeders may act as bio-accumulators. In some cases, their activities may enhance local environmental quality, but this may be a mixed blessing. Oysters and other edible mollusks, for example, are excellent at extracting bacteria and other microbes from the water, but if those microbes include fecal coliform bacteria from human sewage the commercial value of the mollusks as food is severely compromised. The array of complex ecological interactions between plants and insects has permitted the classification of insects as "beneficial," meaning that they do not compete with us for plant biomass, "pest," meaning that they do compete with us for plant biomass, or "vector" when they transmit diseases to us or our livestock. We use parasitoid insects as agents of biocontrol by infecting pests and vectors with them.

III. SUMMARY

Organismal diversity is not just amazing, it is important. The extent to which parts of today's planetary array of organisms can be reduced without creating a cascade of extinctions is unknown but hotly debated. It is known that virtually every species has some value to humans, either directly or indirectly. Organisms provide us with food, shelter, raw materials, things of beauty, and pharmaceuticals; help us with our work; and maintain the ability of our air, soil, and water to sustain life, including our own. They are valuable to us indirectly as the building blocks of the biosphere within which we originally evolved and which we still require in order to survive.

There is also clear evidence that all organisms are intimately tied together in the structure of the biosphere because they are all simultaneously parts of larger genealogical and ecological wholes. The significance of the duality of organismal diversity is most apparent in the recognition that new types of organisms are derived from preexisting organisms, while at the same time almost all organisms make extensive use of the biodiversity that predated their origins. Newly evolved organisms always have an impact on preexisting ones. Because it is in the nature of the organism to be relatively autonomous from its surroundings, these interactions are not necessarily positive, often taking the form of
“conflicts of interest.” The evolutionary resolution of these conflicts of interest has produced an increasingly complex biosphere. As Maynard Smith and Szathmary (1995) observed, each major transition in evolution has been associated with the emergence of organisms, and by extension the entire biosphere, with enhanced abilities to produce, maintain, and transmit information cohesively and also associated with the emergence of novel forms of selection resulting from the evolution of those new organisms. In this way, each newly evolved form of organism becomes intimately involved with both local and global ecology, maintaining the biosphere as a relatively isolated system with its own windows of viability (Ulanowicz, 1997).

GLOSSARY

functional diversity The different types of processes in a community that are important to its structure and dynamic stability.
functional group A group of species that utilize similar resources; synonymous with guild.
guild A group of species that utilize similar resources (usually food).
species evenness A measure of the relative abundance of species in an area.
species richness The number of species in an area.
species turnover The change in the composition of species in an area due to the extinction of some species and the replacement by a new species by colonization.
taxonomic diversity The number and the relative abundance of species in a community.

TAXONOMIC DIVERSITY refers to the number and the relative abundance of species in a community. Functional diversity refers to the different types of processes in a community that are important to its structure and dynamic stability. Taxonomic and functional diversity have been presented as being different, and as the title implies, competing approaches to the study of biodiversity. This article will provide specific examples of how taxonomic and functional diversity are interrelated and how information from both perspectives can be used to estimate biodiversity and propose mechanisms that govern biodiversity.

I. SPECIES, COMMUNITIES, AND ECOSYSTEMS

Linnaeus (1735) and Hutchinson (1959) provided a convenient starting point to address biodiversity in terms of taxonomic and functional diversity. Linnaeus formalized the two kingdom scheme of Plantae and Animalia and made the distinction between sessile photosynthetic plants and motile food-ingesting animals. Predating an understanding of photosynthesis or modern evolutionary theory, this work was descriptive and simply attempted to categorize and count organisms rather than posit mechanisms. Function was at the basis of the classification. In his address to the Society of American Naturalists, Hutchinson, like Linnaeus, made
a deliberate distinction between primary producers and heterotrophs by asking "why are there so many kinds of animals?" The unique feature of this address was that it studied biodiversity by invoking principles from ecology and evolution, formalizing niche theory, and including energetics. More important, it marks an early attempt to link species diversity to the functioning of an ecosystem.

The choice of taxonomic versus functional diversity illustrates a broader issue in science. In both cases, traditional taxonomies based on individual traits or ones based on the functional attributes of a species in a community or ecosystem are human constructions. Erhlich and Holm (1962) summarized the dilemma nicely:

> There seems to be no theoretical reason why there must be complete congruence among estimates of relationships based on characters from different developmental stages or on characters from different organ systems of the same stage, ... In a taxonomy based on ecological requirements, whales will be more closely related to sharks than to bears. Such a relationship is no more or less "true" than the classical one: It is merely based on different attributes.

At some point the question comes down to the type of information that is used, the way the information is used, and why the information is used.

### A. Different Approaches to Studying Biodiversity

There are different subdisciplines within ecology: autecology (individual/population ecology), community ecology, and ecosystem ecology. The focus and approach of each subdiscipline and the type of information used by each have influenced the degree to which taxonomic or functional diversity have been used (Table 1).

### 3. The Ecosystem Approach

The ecosystem approach defines diversity in terms of processes and function within the community. The focus is not on species per se but rather on the products of species interactions, usually different forms of carbon or nitrogen. Underlying this approach is the belief that species interact in ways that reinforce stabilizing feedbacks that operate to maintain a persistent steady state. The feedbacks operate through the availability of nutrients in one pool of that critical to another pool.

A typical description of an ecosystem does not include many species (except for the dominant species) but rather aggregates of species that are similar in the ways in which they process matter relative to a key process. For example, the decomposition of pine needles on a forest floor is a complex process that is influenced by the nutrient quality of the pine needles, the temperature and moisture of the forest floor, and the organisms that are present. For the microbes alone, the process might involve more than 100 species of saprobic fungi and an equal number of strains of saprobic bacte-
ria. Depending on the level of resolution desired, the microbes could be aggregated into a single pool of "decomposers" or separated into pools of "fungi" and "bacteria." The justification for the seemingly casual treatment of the individual species is that the focus is not on how many species are present but rather on the general composition of the pool and the rate at which the pool processes matter.

II. SPECIES, FUNCTION, AND THE ECOLOGICAL NICHE

Taxonomic and functional diversity use similar information but in different ways. The species is central to taxonomic diversity. Species are arranged into phylogenetic relationships that are based on how they acquire energy, their cell types, the level of cellular organization, their embryology and life history, their physiology, and their genetic makeup (RNA and/or DNA). Different classification schemes have been proposed that use all or some of these criteria with different weights given to any one of the criteria. Ecosystem processes are central to functional diversity. Functional diversity has been based on ecological characteristics. Species are aggregated into functional units based on how they use resources. Various schemes have been proposed to aggregate species into functional groupings. Species are arranged into functional relationships based on how they acquire energy, where they acquire energy, the rates at which they process energy (physiology), and when they process energy (life history).

Linking taxonomic and functional diversity would require integrating information that describes the makeup of an organism (its taxonomic characteristics) along with the rates at which it processes and transforms matter (its functional characteristics). Niche theory offers a way to link taxonomic and functional diversity.

A. The Ecological Niche

The ecological niche of a species is defined by the resources it requires. The niche of a species can be viewed graphically as a hypervolume, in which each resource represents an independent axis (Fig. 1). The space that each species occupies within this hypervolume is defined by its resource requirements. An analysis of the resource requirements for several species from different taxa revealed that the principal niche axes are food, habitat use, and time.

B. Functional Groupings of Species

Both the community and the ecosystem perspectives have grouped species into larger units when studying interactions among species or processes mediated by species. The schemes used have ranged from ones of convenience, which are usually based on a broad taxonomic category, to ones that have adopted strict criteria that may include organisms from different taxonomic groupings. For this discussion, the groupings that have been based on the resource requirements of a species and its position in niche space relative to other species makes the most sense, given that function in an ecosystem context is directly related to how species utilize resources. Hence, a functional group is composed of species that utilize similar resources (Fig. 1). There is no standard number of resources (axes in niche space) used to establish functional groups, but many are based on the principal resources of food, habitat, and time. This has resulted in the groupings being given different names. For
example, a "guild" is defined as a group of species that feed on similar food in a similar way. Soil ecologists define a "functional group" as a group of species that feed on similar food in a similar way, occupy the same habitat, and possess similar life histories.

III. ESTIMATING DIVERSITY

Procedures to estimate species diversity originated from the fields of information theory and statistics. If presented a code with a set number of symbols (s) of known proportions (p), it is desirable to estimate its information content. Ecologists simply substituted the species (or aggregations of species) for the symbols. Species diversity of a community could be estimated in the same way as the information content of a code. Two aspects of species diversity are the number of species (species richness) and the relative abundance of species in a community (species evenness).

A. Species Richness

Species richness (S) is the number of species within a defined region. The species richness of a region is obtained through sampling or via a census. Because "region" is defined by the observer, species richness has been further categorized into three components to account for changes in spatial scale.

Alpha diversity, sometimes referred to as point diversity, is the species richness that occurs within a given area within a region that is smaller than the entire distribution of the species. Beta diversity is the rate at which species richness increases as one moves in a straight line across a region from one habitat to another habitat. In other words, it is the rate of change in species richness that occurs with a change in spatial scale. Gamma diversity is the species richness within an entire region. As the area being surveyed approaches that of the entire region, alpha diversity approaches gamma diversity and beta diversity approaches zero.

B. Species Evenness

Species evenness takes into account the number of species and the relative abundance of species in a community. Several indices have been proposed. Two of the commonly used measures of evenness are the Shannon index (H) and the Simpson index (D).

The Shannon index (H) is a measure of the information content of a community rather than of the particular species that is present. The index is as follows:

\[ H = -\sum_{i=1}^{s} p_i \log p_i \]

where s is the number of species in the community (species richness) and \( p_i \) is the relative proportion of species i. Hence, if two communities (A and B) with the same number of species (not necessarily the same species) present were compared, and the distributions of \( p_i \) were the same, then \( H_A = H_B \). On the other hand, if either the number of species or the proportions differed, then \( H_A \neq H_B \). In the latter case, the community with the greater number of species whose relative abundances were equal would possess the higher diversity.

The Simpson index (D) measures the dominance of a multi-species community and can be thought of as the probability that two individuals selected from a community will be of the same species. The Simpson index was originally proposed as follows:

\[ D = -\log \sum_{i=1}^{s} p_i^2 \]

where s is the species richness of a community and \( p_i \) is the relative proportion of species i. The index can be modified to \( 1 - D \) to give it the property of increasing as diversity increases (the dominance of a few species decreases).

C. Linking Species Richness and Species Evenness

Species richness and species evenness are special cases of dichotomous-type rarity measures. For dichotomous-type rarity measures for a pool of s species, the rarity of species i, whose function is denoted \( R(p_i) \), depends only on its relative abundance \( (p_i) \). The rarity measures \( \Delta \) take the following form:

\[ \Delta = \sum_{i=1}^{s} p_i R(p_i) \]

The relationships between species richness \( (S) \), the Shannon index \( (H) \), and the Simpson index \( (D) \) are
presented in Table II. Notice that the indices share three important properties: (i) $\Delta$ is maximized when $p_i = 1/s$ for all species; (ii) given that $p_i = 1/s$, the community with the higher species richness has the greater diversity; and (iii) $\Delta = 0$ if the community possesses a single species ($s = 1$).

### IV. BIODIVERSITY AND SYSTEMS THEORY

One of the enduring tenets of ecology in the early part of the twentieth century was that a diverse community was a stable community. The linkage between biodiversity and stability has an intuitive appeal. The more species there are in a community, the more likely they would be tightly networked, and hence the more stable the community would be. Interestingly, function plays an important role in this argument in that in a highly diverse community, there would be alternative species or assemblages of species to perform key tasks to sustain the cycling of matter and the current diversity. These ideas have been challenged and modified. Ecologists agree that biodiversity is important to the function and stability of an ecosystem. The current debates center on the nature of the relationship between biodiversity, function, and stability.

Although useful, the functions used to estimate biodiversity that were presented previously are descriptive measures and imply neither the mechanisms that shape biodiversity nor the importance of biodiversity to maintaining the structure and dynamic stability of a community. If the diversity of one community were higher than that of another, does this increase its likelihood of persisting in time or recovering from a disturbance? The answer depends on the species involved. For example, the colonization of an exotic species increases the species richness of a community but does not necessarily increase its stability—to the contrary, it often destabilizes the system. On the other hand, the addition of a predator can stabilize an ecosystem by tempering the oscillations in the population densities of its prey through time. Biodiversity is a property of complex dynamic biological systems. The steady state and stability are two concepts important to the study of complex dynamic systems.

#### A. The Steady State

A steady state is an equilibrium condition in a dynamic process in which the rate of input of a state variable is equal to the rate of output of that variable (Fig. 2). The dynamic process can involve any variable that changes in time. For taxonomic and functional diversity, the variables of interest are the number of species or functional groups, the densities and biomass of each species or functional group, and the mass of key elements within different pools within the ecosystem.

1. **The Number of Species**

The number of species in a community is at steady state when the rate of colonization equals the rate of extinction (Fig. 3). The classic model of this process, the theory of island biogeography (MacArthur and Wilson, 1967), assumes that the rate of colonization is affected by the distance that the habitat being colonized is from the source of species and by the size of the habitat being colonized. Colonization rates are higher for large habitats that are close to the source of species than for smaller distant habitats. The rate of extinction is affected by the size of the habitat. The rates of extinction for smaller habitats are higher than those for larger habitats.

2. **Species Composition**

In the model presented previously, although the number of species is constant at steady state, the species composition of the community does not remain constant. The model simply assumes that once the rates of colonization and extinction are equal, then for every new species that enters a habitat, one of the current resident species goes extinct. This point is important when trying to estimate the diversity of a habitat by sampling the habitat over time. If a habitat were sampled long enough, the estimate of the number of species within the habitat would equal the number of species in the habitat serving as the source, even though the source has a higher number of species at its steady state than the habitat being colonized.

3. **Population Densities**

The population density of an individual species within a habitat is at steady state when the number of births
and immigration equal the number of deaths and emigration. When modeling this process, ecologists typically assume that the habitat is closed to immigration and emigration and focus entirely on the rate of birth and the rate of death. More sophisticated approaches that involve multiple habitats will include the immigration and emigration of species among habitats.

4. Community Structure
A community is at steady state when the species composition of the community and the densities of the species remain constant. This implies that the species richness and evenness of the community do not change. This condition is rarely met since the species composition and the densities of the species fluctuate through time.

5. Ecosystem Processes
An ecosystem process is at steady state when the rate of input of matter or energy is equal to the rate of output. The input of matter and energy occurs via photosynthesis and from sources external to the ecosystem (e.g., leaves entering a stream). The export of matter and energy occurs through heterotrophic respiration and the physical movement of matter from the ecosystem (e.g., export of leaves from forest to a stream). The production of organic matter from inorganic matter (photosynthesis) and the transformation of organic matter to other organic forms and inorganic matter (heterotrophic respiration, hereafter referred to as respiration) are ecosystem processes that approach a steady state and illustrate the interplay between matter and energy. When the rate of photosynthesis equals the rate of respiration, the system is said to be at steady state.
not disagree that dynamic stability affects biodiversity, yield different results with regard to the nature of the relationship.

The concepts of local stability and the theory of island biogeography may seem at odds with one another, even though they rely on similar mathematics and assumptions and are modeling the same systems. An obvious question is, how can an ecosystem be locally stable if the species composition of the ecosystem is changing? The discrepancy can be clarified by revisiting the processes that are being modeled. When modeling populations within a community, local stability is in reference to the densities or biomass of the populations. The dynamics of the populations are governed by the difference between the rates of birth and death. When modeling the species diversity within the same community, local stability is in reference to the number of species that are present. The dynamics of the number of species is governed by the rates of colonization and extinction. To carry this a step further, the local stability of the carbon or nitrogen cycles within an ecosystem is in reference to the mass of the different forms carbon or nitrogen. The dynamics of the different forms is governed by the functional attributes of the species present and the rates at which the different forms are acted upon.

2. Resilience

Resilience is a measure of a stable system’s ability and the time required to recover from a minor disturbance. The principle of resilience can be applied to any state variable present in an ecosystem: population densities, the number of species, or the mass of nutrients. Resilience is a function of the rates of inputs of the state variables, the rate at which the state variables turn over, and the number of state variables.

The return time of a system is a measure of its resilience. More resilient ecosystems have shorter return times than less resilient ones. Return time is estimated as the time between the point when the disturbance altered the ecosystem and the point at which the ecosystem recovers. The persistence of a system is compromised if the frequency of disturbance is too great given the length of return time because a system may not have time to recover from any one incident.

3. Oscillations

The state variables of most ecosystems do not maintain a constant steady-state condition but rather they exhibit oscillations. Oscillations are fluctuations in the magnitude of a state variable through time that can be intrinsic to the dynamics of the system in the absence of a distur-
bance or can occur during the recovery phase of a system following a disturbance or both. The degree to which a system oscillates can affect its stability, persistence, and diversity. For example, if the amplitude of oscillations are too great or are such that the population size of a species approaches zero, then the likelihood of that species going extinct increases.

C. Modeling Species Interactions

Gardner and Ashby (1970) presented a simple mathematical exercise that illustrated how the number of interacting units (species) within a system and the number of interactions between these units (species interactions) related to the stability of the system. The exercise constructed simple systems of 4, 7, and 10 units assumed to be at a steady state. For a system of a given size, connections were made between the units in a way that ensured that all units would be connected to the system, creating several variations of the system in terms of the connections. Next, the strength of the connections was allowed to vary, and the systems were disturbed by moving the units away from their steady state. Two results emerged from their work. First, as the number of interacting units increased within a system the likelihood of the system returning to a steady state after a small disturbance (stability) decreased. Second, for a given number of interacting units, as the number of connections between the units increased, the stability of the system declined.

There is a clear connection between the simple mathematical exercise presented above and the diversity and stability of ecological communities (May, 1973). The species is substituted for the generic units modeled previously, and the interactions are defined in terms of predation, competition, or mutualism. Like the generic modeling exercise, high biodiversity does not necessarily lead to stability. Additional studies demonstrated that systems composed of species aggregated into blocks of highly interactive species that were connected by weaker interactions were more stable than systems with the same number and types of species and interactions arranged at random. Hence, the way in which the community is constructed affects its diversity and stability.

The types of interactions among species affect the stability of a community. Theory and observation agree in general terms on this point, if not on specifics. For example, mutualistic interactions, whereby the actions of each species benefit the growth and dynamics of one another, and omnivory, in which species derive energy from different trophic levels, have been shown to be destabilizing in simple models, but both are prolific in natural communities. All the dominant terrestrial ecosystems rely on a mutualism between the vascular plants and microbes, and nearly every described ecosystem possesses numerous examples of omnivory.

D. Modeling Species and Processes

Process-oriented models focus on the transformation of elements among various inorganic to organic states through ecosystems. Carbon, nitrogen, and phosphorus are the more common choices of elements to be modeled given their importance to plant and animal growth. Models of species interactions have been connected to models of processes. The general approach to linking these models is to use the structure and formulation adopted when modeling species with the currency used in models of processes. First, species are aggregated into functional groups using one of the schemes described previously, and the interactions among the functional groupings are established. Second, the biomass, expressed in terms of carbon, nitrogen, or phosphorus, of each functional group is estimated. Third, a series of differential equations is developed that establishes which functional groups interact with one another and the nature of the interactions. Parameters within the models include birth and death rates, feeding rates, and the efficiencies by which the functional groups convert consumed matter into new biomass. The models are used to estimate the flow of elements among the functional groups, the flow of elements out of the system, the stability of the ecosystem, and the resilience of the ecosystem.

Three results have emerged from these models. First, the models are sensitive to the changes in the parameters associated with the physiology and life histories of the species within the functional groups. For example, microbes possess high reproductive rates and high rates of energy conversion, and they process matter at a higher rate compared to a functional group dominated by arthropods or nematodes, which possess lower reproductive rates and rates of energy conversion. Second, functional groups are arranged into interactive blocks that form pathways of material flow that originate from a specific source and end with a top predator. The blocked arrangement of functional groups, the distribution of biomass within the ecosystem, and the distribution of the flow of elements through the ecosystem influence the stability and resilience of the system.
V. LINKING TAXONOMIC AND FUNCTIONAL DIVERSITY

The linkage between taxonomic diversity and functional diversity involves many facets. The morphology of an organism determines the type of habitat in which it resides and its ability to colonize new habitats. The physiology of a species influences its adaptiveness to a habitat and the rates and efficiency with which it transforms matter. The life history of an organism influences the rate at which it processes matter (births, deaths, and consumption). Linking taxonomic diversity to functional diversity requires finding measurable attributes that all organisms possess that have meaning to all the ecological subdisciplines, but it also requires flexibility in terms of how the information is used. Three case studies are presented in the following sections. The case studies illustrate how, when studying biodiversity, aspects of both taxonomic and functional diversity are used interchangeably.

A. Diversity of C₃ and C₄ Grasses

The first case study involves a comparison of the distribution of grass species that possess either the C₃ or C₄ photosynthetic pathways in North America. The study illustrates how the information of autecology can be used to find mechanisms to explain patterns in diversity. The study demonstrates how the functional aspects of an organism's physiology influence a species' adaptability to a habitat and ultimately the diversity of species with similar physiologies.

Plants that possess C₃ and C₄ photosynthetic pathways differ in terms of their morphology and biochemistry as they relate to the dark reaction of photosynthesis. For C₃ plants, photosynthesis occurs entirely within the outer mesophyll cells, in which CO₂ enters the Calvin-Benson cycle through the plants' stomata. The enzyme (RuBP carboxylase or Rubisco) that incorporates CO₂ into the Calvin-Benson cycle also has an affinity toward O₂. If O₂ were incorporated instead of CO₂ the plant would experience photorespiration—energy is expended, no carbon is fixed, and the plant loses organic carbon. For C₄ plants, there are two types of photosynthetic cells: the outer mesophyll cells and the inner bundle sheath cells. In C₄ plants, CO₂ enters the mesophyll through the stomata and is incorporated into a four-carbon compound before being exported to the bundle sheath cells in which it enters the Calvin-Benson cycle. The additional steps that occur within the C₄ plants prior to the Calvin-Benson cycle cost the plant additional energy and organic carbon. However, the enzyme (PEP carboxylase) that adds the CO₂ to the four-carbon molecule in the mesophyll cells is more efficient than Rubisco and less likely to initiate the loss of organic carbon to photorespiration. This trade-off places plants with the C₃ pathway at a disadvantage under cool and moist conditions compared to those with the C₄ pathway, but it affords them an advantage in warmer and dry conditions.

Within North America, the northern latitudes are dominated by species of C₄ grasses, whereas the southern latitudes are dominated by species of C₃ grasses. This pattern of diversity has been attributed to the adaptiveness of each pathway to patterns of temperature and light intensity. The lower latitudes possess higher temperature and higher light intensity than the upper latitudes given the orientation of the earth to the sun. Grasses that possess the C₃ pathway have been shown to be more productive than those with the C₄ pathway under conditions of cool temperature and low light intensity. At higher temperatures and light intensity, C₃ plants suffer greater water loss through their stomata and increased photorespiration than do C₄ plants.

B. A Test of the Theory of Island Biogeography

This case study illustrates how information from the community perspective has been used to study biodiversity. The experimental manipulations of several small mangrove islands off the Florida coast by Simberloff and Wilson (1969a, b) and the reanalysis of their work by Heatwole and Levins (1972) offer not only the best validation of the theory of island biogeography but also some insight into how taxonomic diversity and functional diversity are related.

Simberloff and Wilson (1969a, b) conducted a thorough survey of arthropods on four small mangrove islands and then fumigated the islands with methyl bromide to eliminate the arthropods. For 2 years following the disturbance, they sampled for arthropods that recolonized the islands. The results were consistent with those predicted by the model proposed for the theory of island biogeography. The colonization rates were higher and the steady states in species richness were achieved sooner on islands closer to the mainland than on the more distant island. Once a steady state in species richness was achieved, the species composition changed due to the predicted turnover in species.

Heatwole and Levins (1972) provided an explicit link between the recovery process, species diversity, and functional diversity. They aggregated the species
into guilds based on the feeding and foraging behaviors of the arthropods (predators, herbivores, decomposers, ants, etc.). One year following the fumigation, the taxonomic diversity of the islands was lower than it was prior to the fumigation (Table III). However, the proportion of species within each of the guilds was the same as it was prior to fumigation. These results suggest that the functional diversity of the islands recovered before the species diversity. In other words, the taxonomic diversity of the communities was in some way dependent on functional characteristics of the community.

C. Invasion of an Exotic Species

The final case study illustrates how elements of taxonomic and functional diversity and information from autecology, community ecology, and ecosystem ecology have been used to study biodiversity. Vitousek and colleagues (1987, 1989) studied the natural history of the invasive plant species Myrica faya and the effects that it has had on the nitrogen cycle and plant community development of recent lava flows in Hawaii. Since its introduction to Hawaii from the Canary Islands by Portuguese immigrants at the end of the nineteenth century, M. faya had colonized more than 34,365 ha. Myrica faya forms a symbiotic association with the soil nitrogen-fixing actinomycete, Frankia. The plant possesses two characteristics that separate it from the native nitrogen-fixing plants on the islands. Unlike the native plant nitrogen fixers (Acacia koa and Sophora chrysophylla), the seeds of M. faya are small, have an edible fleshy fruit, and pass through the digestive systems of birds intact. Moreover, M. faya is a more efficient nitrogen fixer than the native species. When combined, these factors make M. faya a superior colonizer of recent lava flows, pastures, and forests.

Once established, the M. faya and its soil symbiont, Frankia, alter the nitrogen status of the soils. For example, soil nitrogen inputs within open canopies of M. faya were four times more than those of similar sites without the exotic plant (23.5 and 5.5 kg per hectare per year, respectively). This added soil nitrogen becomes available to other plant species, facilitating invasions by other exotic species (e.g., strawberry guava, Psidium cattleianum) to the detriment of native plant species. The functional attributes of a single species and its symbiont affected the biodiversity of a community by altering the course of community development.

VI. NATURAL SELECTION

Species evolve and communities and ecosystems change, but do communities and ecosystems evolve? Does natural selection operate on communities and ecosystems even though they do not possess genes? Natural selection needs to be defined before these questions can be answered. Natural selection is the differential perpetuation of genes in successive generations caused by different degrees of adaptiveness to the environment.

One argument is that ecosystems do evolve because the composition of species within a community changes and natural selection operates on the gene pools of each species. In addition to the changes in the genetic makeup of the species, there are changes in key processes that feed back to reinforce stable configurations or that initiate change. A criticism of this analogy is that natural selection at the ecosystem level for the type of coordination among species that leads to a stable ecosystem is not the same as selection at the organismal level on genes. Selection on genes operates through differential reproductive success of individuals, whereas this may not be true at the ecosystem level since the boundaries of an ecosystem are not so clearly defined.

An alternative view posits that ecosystems do not evolve, but that the species composition of the stable ecosystem is a result of the selection operating on individuals and the coevolution of species interacting with one another. The outcome of selection on individuals

can influence function within a community, which in turn feeds back as a form of selection. Unique to this argument is that the adaptiveness of a species includes the degree to which its dynamics and function contribute to and are compatible with the stability of the ecosystem as a whole.

I. Introduction

The original focus of farming was on growing food crops, but this was soon extended to include plants essential for other utilities such as fiber sources, stimulants, medicinal aids, dye crops, forage, and timber production. In addition, the past two or three centuries witnessed another major development, namely a massive introduction of ornamental plant species into cultivation. (Today the number of ornamental species exceeds the number of food crops.) Most recently, plants with medicinal properties are getting new attention. The potentials of scores of such plant species (traditionally collected from the wild) have been evaluated. To ensure a steady supply, and for improving quality and yields, many of them are presently introduced into cultivation.

A parallel trend is apparent in forestry. Here, too, dozens of timber producing trees are being quickly domesticated. To date, thousands of plant species, native to the various phytogeographic regions of the World, have been introduced into cultivation. In the majority of these cases, the domestic derivatives have already been drastically altered by this move. So much so that the cultivated forms can no more survive in the wild and have become dependent on humans for their existence. Grain crops, for example, lost the wild type adaptation to disperse their seeds and depend on the harvesting, threshing, and sowing by the farmer. Vegetatively propagated tuber plants (under domestication) are commonly sterile. So are many seedless varieties of fruit crops (e.g., bananas). Moreover, as a result of (a) the ecological shift from the original wild habitats into the greatly different and varied anthropogenic environments and (b) repeated cycles of deliberate selection by humans, many domesticates have greatly diverged.
under domestication. In most major food crops (e.g., bread wheat, rice, maize, apple, or grapevine) or in many popular ornamentals (e.g., roses, rhododendrons, narcissi, tulips, irises), hundreds or even thousands of distinct cultivated varieties (“cultivars”) or ornamental forms are now recognized, fitting the wide range of conditions under which these plants are being maintained and the different and contrasting wishes of the growers who constantly try to improve their plants by selection. All in all, domestication provides us with most impressive examples of rapid evolution in plants. Vast arrays of morphological, anatomical, physiological, and chemical changes have evolved in crops and ornamentals, and this in a very short span of evolutionary time. Moreover, selection under domestication molded the gene pools of the crops (the “cultivated gene pools”) to become the backbone for the production of food and other essential utilities for humankind. Today, our very existence depends on this genetic diversity. Thus not only do the crops become dependent on humans; also humans became dependent on crops. Obviously, civilizations and domesticated plants have coevolved; and this coevolution continues today.

II. THE TRADITIONAL AGRICULTURAL SYSTEMS OF THE WORLD

In classical times (about 2500–2000 years ago), and to a large extent until Columbus’s time, agriculture was structured quite differently from what we find it today. At present, each country grows a mixture of crops introduced from the various parts of the world. But this fusion is very recent. Traditionally, farming was practiced in largely separated, independent regions, each occupying extensive territories and each possessing a characteristic and largely unique ensemble of native crops. When the Europeans discovered America, they found that the flourishing agricultural civilizations in the New World were based on growing crops that were totally different from what they were familiar with in Eurasia and in Africa. The two hemispheres are indeed very rich in cereals, pulses, tubers, fruits, vegetables, spices, and other types of cultivated plants. Yet the list of domesticated plants in each of them is unique. With only one or two exceptions, these two landmasses originally had no crops in common. This strongly indicates that domestication and agriculture in each of them evolved independently.

Also within each of the two hemispheres, one can detect similar patterns. Each landmass seems to contain several historical agricultural regions, previously separated by difficult-to-cross geographic and cultural barriers. Thus the crops of the traditional agriculture system in Southwest Asia, the Mediterranean basin, and temperate Europe were very different from those grown in East Asia. Moreover, the crop composition in each one of these two agricultural systems is very different from the crop assemblage in Africa south of the Sahara. Similarly in the New World, numerous crops grown in South America were not known in Mexico and middle America, and vice versa.

The main food crops in the traditional agricultural regions of the world are given in Appendix 1. A comparison between the various regional lists of crops reveals that each agricultural system usually contains dominant cereals, companion pulses, oil plants, fruit crops, vegetables, spices, tubers and corms, and stimulants. In other words, the composition of crop blends repeats itself. Only the plant species are different in each traditional region (for example, wheats and barley, lentil, and pea in Southwest Asia, the Mediterranean basin, and Europe; rice and soybean in East Asia; maize and Phaseolus beans in America; and sorghum and other millets and cowpea in Africa south of the Sahara).

III. THE EMERGENCE OF AGRICULTURE

The shift from hunting and gathering to farming started relatively very late in the history of Homo sapiens. The archaeological and botanical evidence already assembled on this development is not even. Some parts of the world (the Mediterranean basin, the Nile Valley, temperate Europe, Southwest Asia, North America) have already been extensively studied. Other parts of the world (East Asia, the Indian subcontinent, South America) are much less explored but at least provide us with some critical evidence on the beginning of agriculture in them. In still others (Africa south of the Sahara, most of the tropical parts of the world) archaeological and botanical information is still very poor or almost nonexistent. Even so, the available information clearly shows that farming was independently initiated in several geographically and culturally separated “nuclear areas,” both in the Old World and in the New World, between 10,000 and 5,000 years before present (a.r.) uncali-
brated radiocarbon time. In each such area cultivation seems to have been independently invented, and native wild plant species—largely unique to each area—were introduced and tested in cultivation. Some evolved to be the ‘founder crops’ that initiated farming in these independent places. Once this new way of life had been successfully established, these domesticates also formed the basis for a territorial expansion of the newly formed agricultural populations and for further development in food production.

A. The First Old World Territory

The oldest and the most extensively studied nuclear area is the ‘fertile crescent’ belt of the Near East. In this rather small geographic territory, a string of early Neolithic farming villages started to appear some 9500 years ago and further established themselves in the subsequent 1500 years. Plant remains retrieved from these early archaeological sites show that eight grain plants growing wild in this Near Eastern ‘arc’ were domesticated at these times. Most common in these pre-ceramic Neolithic Near Eastern sites were remains of three cereals: emmer wheat, einkorn wheat, and barley. They were accompanied by pulses (lentil, pea, chickpea, bitter vetch) and by flax. Soon later, by 8900–8600 n.r., signs of domestication of sheep, goat, cattle, and swine appeared in the sites as well, and the Near Eastern “package” for food production was formed. Once the package was assembled, and the early Neolithic farming villages were soundly established, farmers started to expand. They did so explosively. By 8000 n.r. this type of agriculture was already introduced into Greece, and by 7000 n.r. it had reached the Danubian basin, the Nile Valley, the Caucasus, and Turkmenistan, and soon afterward it was introduced in the Indus basin. By 6500 to 6000 n.r., grain crop agriculture (and cattle and caprine rearing) was already established all over major parts of temperate Europe—from Ukraine in the east to northern France in the west. More or less at the same time, this new technology also appeared in the middle and western parts of the Mediterranean basin as far as south Spain. All over these vast territories of Southwest Asia, the Nile Valley, the Mediterranean basin, and temperate Europe, agriculture was started by the introduction of the same Near Eastern crops (wheats and barley, and their companion pulses and flax). Only later were additional plants, native to other parts of this huge region, added (e.g., poppy Papaver somniferum in the west Mediterranean basin)

Some 3000 years after the start of Neolithic grain agriculture, fruit crop horticulture (based on the invention of vegetative propagation) appeared in this region. As with grain crops, the earliest convincing signs of fruit tree cultivation were found in the Near East. Olive, fig, grapevine, and date palm have been cultivated here at least since Chalcolithic times (5500 n.r.). Horticulture, too, spread quickly. By the late Bronze Age, olive, grapevine, and fig (as well as pomegranate and almond) were already used as principal elements of food production in the Aegean belt; and date palm groves flourished in the warm fringes of the Near East and the eastern Mediterranean basin (including Egypt) and extended eastward as far as the Indus Valley.

From the Bronze Age onward there are sound indications of cultivation of vegetables. Melon, watermelon, onion, garlic, leek, and lettuce were the first vegetable crops grown in Mesopotamia or in Egypt. Definite signs of their cultivation appear by 4500 to 3300 n.r. By 2800 to 2000 n.r., the list of Mediterranean and Southwestern Asian vegetable crops had grown considerably; and beet, turnip, cabbage, radish, carrot, parsnip, celery, parsley, and asparagus had also entered cultivation. More or less at the same period (2400–2000 n.r.), a second group of native fruit trees (those in which cultivation depends on grafting) was also added. Most conspicuous among them are apple, pear, plum, and cherries. Contrary to the earlier crops that were almost all taken into cultivation in the Near East “arc,” many of the vegetables and the late fruit trees were probably picked up for domestication, not in the Near Eastern nuclear area but in other parts of the already vast Mediterranean and Southwest Asian system of agriculture.

Thus, starting in the Neolithic and ending in classical times, an impressive assemblage of native crops were domesticated and diffused all over Southwest Asia, the Mediterranean basin, and temperate Europe. Most of them remained economically important until today.

B. The Second Old World Territory

A second Asian nuclear area—or more exactly two closely situated, but independent initiations of farming—have been discovered in East Asia. The first was uncovered in the loess soil belt in Honan province and adjacent areas, in the middle part of the Yellow River Valley in North China. The second in the Hupei basin.
in Central China, along the middle Yangtze River, and also in the wetlands of its delta. The evidence available on the start and on the subsequent development of agriculture in China is still fragmentary compared to that available on the Near East. Yet very ancient farming villages have been discovered both in the northern and in the central parts of this large country. They represent the oldest undisputed signs of plant domestication found yet in East and in South East Asia.

In the Yellow River Valley the oldest farming sites date from 8800 to 7000 B.P. and they contain very large amounts of foxtail millet, indicating that in temperate North China this cereal had been the principal founder crop of the local agriculture. Also in later times foxtail millet continues to be a major food crop in China. More or less in the same time, farming villages seem to have appeared in the middle of the Yangtze River Valley. The earliest sites discovered there date even somewhat older (8500–7000 B.P.) than those in north China. Significantly, in these sites the dominant crop is rice, which later emerges as the most important crop of the vast agricultural economies of East and Southeast Asia. Massive remains of this cereal were unearthed in the Hupei basin, and they continue to appear in the Yangtze River Valley and in later archaeological contexts. These are the oldest remains of rice found yet. But because they occur on the fringe of the wild rice distribution area, some workers suspect that even older rice sites will be discovered in the future further south.

C. The Third Old World Territory

A third territory in the Old World suspected to have had an independent initiation of agriculture is the Savanna belt and its forest margin in Africa south of the Sahara. The traditional agriculture in this region (which stretches from Senegal and Guinea to Sudan) is based, almost entirely, on a rich assemblage of native crops such as sorghum, pearl millet, African rice, fonio, cowpea, and bambara groundnut (Appendix 1). The highlands of Ethiopia border the Savanna belt in the east and also harbor an impressive list of local crops, such as teff, finger millet, coffee, and noog. But here the African plants grow side by side with wheat, barley, and many other Near Eastern elements that reached Ethiopia in the past. All in all, African agriculture is diverse and adapted to a wide range of situations. Apart from the Near Eastern elements in Ethiopia, its rich crop assemblage seems almost fully indigenous. This is borne by the fact that the wild relatives of the crops are restricted in their distribution to this part of the World. Most of them could have been introduced into cultivation only somewhere in this geographic belt. All this seems to suggest the independent initiation of cultivation. Whether this is indeed the case is yet hard to say. Archaeologically, Africa south of the Sahara is practically unexplored. The few data available on cultivation of pearl millet or other crops are no more than 3000 years old.

D. The American Territory

There is little doubt that farming was independently invented in the Americas. As already noted, in pre-Columbus times the Eastern hemisphere and the Western hemisphere shared almost no crop in common. On basis of this evidence it is hard to imagine agricultural contacts between the two landmasses before that time. Also in America itself archaeological research has revealed definite signs of early cultivation, not in a single area but in several distant locations.

Indications of early, possibly independent initiation of cultivation come from South America. Chemical comparisons have shown that the common bean and lima bean were independently domesticated both in the middle and in South America. Finds in the central and south Andes show that potato and Quinua cultivation in these elevated areas might be 5000 years old, although dating is yet problematic. Finally, sound evidence has been assembled that independent domestication of plants took place in eastern North America. Here goosefoot Chenopodium berlandieri, sunflower, and marsh elders were cultivated at least 4000 to 3500 years ago. This is some 2000 years before maize or any other outsider crop reached this area.

IV. REPRODUCTIVE SYSTEMS IN PLANTS UNDER DOMESTICATION

Cultivated plants differ markedly from wild plants in the way by which they are reproduced and maintained.
In the various families of the flowering plants, cross-pollination is the principle genetic system. Most species build out-breeding populations. Other reproductive systems such as self-pollination and vegetative propagation (including apomixis) occur as well and are even common in some genera and families. Yet compared to sexual reproduction by cross-pollination, their overall weight is small. In contrast, cross-pollination is relatively rare in plants under domestication. Most crops are maintained by one of the following two systems: (a) self-pollination and (b) vegetative propagation. In contrast to cross-pollination, both these reproductive systems are effective in bringing about immediate ‘fixation’ of desired genotypes.

A. Self-pollination

Self-pollination, or more exactly almost full self-pollination, is the principle mating system found in grain crops and in many vegetables. The majority of the 50–60 main grain crops of the world are predominantly self-pollinated. Only a few (such as maize, rye, pearl millet, buckwheat, or scarlet runner bean) are cross-pollinated. Now that the wild progenitors of the majority of the grain crops are already satisfactorily identified, we know that the wild ancestors of the self-pollinated crops are also self-pollinated. In other words, self-pollination in grain crops did not evolve under domestication. It is rather a ‘preadaptation’ of the wild ancestor, which considerably enhances its chance to perform successfully in cultivation. One major advantage of self-over cross-pollination is the fact that self-pollination isolates the crop reproducitively from its wild progenitor. It enables the farmer to grow a desired genotype in the same area in which the wild relatives abound without endangering the identity of the cultivar by genetic swamping. A second advantage of self-pollination lies in the genetic structure maintained within the crop. Self-pollination results in splitting the crop’s gene-pool into independent homozygous lines. Variation is thus structured in the form of numerous true breeding cultivars. Because they are automatically ‘fixed’ by the pollination system, they can be easily maintained by the farmer, even if they are planted together. In contrast, the preservation of varietal identity in cross-pollinated plants is much more problematic. It requires repeated selection towards the desired norms, constant care to avoid the mixing of types and the prevention of contamination from undesirable plants. It is therefore not surprising that early successes in plant domestication frequently involved selfers. In fact, all the eight Neolithic Near Eastern founder crops have this system of reproduction.

B. Vegetative Propagation

Vegetative propagation is the second widely adapted means to fix and maintain desired genotypes under domestication. This way of handling prevails in the fruit trees, in tuber and corn crops, and in numerous ornamentals. Here, domestication means first of all changing the reproductive biology of the plants involved by shifting from sexual reproduction (in the wild) to vegetative propagation (under cultivation). As a rule, cultivated varieties of these plants have been maintained as clones by cuttings, rooting of twigs, suckers, or by the more sophisticated technique of grafting (and recently also by meristem tissue culture propagation). This is in sharp contrast with their wild progenitors, which reproduce from seeds. Their wild growing populations are usually variable, maintain themselves through sexual reproduction, and are distinctly cross-pollinated. Consequently, seedlings raised from any mother plant segregates widely in numerous traits, including the size, shape, and palatability of the fruits or the tubers.

In the hands of the grower, vegetative propagation has been a powerful device to prevent genetic segregation and to ‘fix’ desired genotypes. By discarding sexual reproduction and inventing clonal propagation, the farmer was able to select, in a single act, exceptional individuals with desirable traits from among a large numbers of variable, inferior plants. Moreover, the farmer could duplicate the chosen types to obtain genetically identical saplings. This is no small achievement. Because the plants are cross-pollinated and widely heterozygous, most progeny obtained from them (even from ‘superior’ plants) are economically worthless. The change from seed planting to vegetative propagation has been a practical solution to assure a dependable supply of desired genotypes. In most fruit trees—and in many tuber crops and ornamentals—it made domestication possible. The history of the Mediterranean fruit trees illustrates this clearly. Olive, grapevine, fig, and date palm that can be relatively simply cloned (by twig rooting, by suckers) were the first to enter cultivation (already by 5500 B.C.). Other native fruit trees that do not lend themselves to easy rooting (e.g., apple, pear, plum, cherry) were domesticatecl much later (about 2400–2000 B.C.). Their incorporation into horticulture became possible only after the invention of a new clonning tool, namely scion grafting.
V. CONSCIOUS VERSUS UNCONSCIOUS SELECTION

Two main types of selection operate (and complement each other) in plants under domestication:

1. Conscious selection deliberately applied by the growers for traits of interest to them.
2. Unconscious selection brought about by the fact that the plants concerned were picked up and isolated from their original wild environment and placed in a new (and usually very different) human-made environment. This shift in the ecology led automatically to drastic changes in selection pressures. In response to the introduction of the plants into the anthropogenic environment, numerous adaptations vital for survival in the wild lost their fitness. New sets of traits were automatically selected for to fit the new conditions, resulting in the buildup of characteristic domestic adaptations and the appearance of "domestication syndromes"—each fitting the specific agricultural system provided by the domesticators.

Although the pressures and the effects of conscious selection in shaping domesticated plants are familiar to both plant breeders and crop plant evolutionists, unconscious selection has been less frequently evaluated. Because this type of selection shapes so many of the principal traits that characterize crops, several developments caused by the shift in the ecology are discussed in some detail in the following sections.

VI. METHODS OF MAINTENANCE OF CROPS AND THEIR IMPACT

As already noted, two main methods of maintenance are employed by the cultivators to maintain their crops: (a) planting of seeds and (b) vegetative propagation. The choice between these two agronomic practices is also the choice between two contrasting patterns of selection and modes of evolution under domestication.

With very few exceptions of apomixis (such as meiotic seed in citrus fruits and mango) planting of seeds can be equated with sexual reproduction. Cultivated plants maintained by seeds (the bulk of the grain crops, numerous vegetables and forest trees, some ornamentals) therefore undergo a recombination-and-selection cycle every planting. In other words, such crops had, under domestication, hundreds or even thousands of generations of selection. They have been continually molded either as (a) clusters of inbred lines (in predominantly self-pollinated crops) or as (b) distinct cultivated races (in cross-pollinated plants). In numerous sexually reproducing crops, the results of such repeated selection are indeed striking. Under domestication these crops have diverged considerably from their wild progenitors. They are now distinguished from them by numerous morphological, developmental, physiological, and chemical traits.

Crops maintained by vegetative propagation (most fruit trees and tuber crops, few vegetables, many ornamentals) have had an entirely different history of selection. Cultivars in these crops are not true races but only clonal replications of exceptional individuals, which are as a rule highly heterozygous. They had been picked up by the cultivator from among numerous sexually produced variable individuals and "fixed" by cloning. In terms of selection, the development of a vegetatively propagated cultivar is largely a single-step operation. With the exception of rare somatic mutations, selection is completed the moment the clone is picked up. In traditional fruit tree horticulture, the turnover of clones has been low. Appreciated genotypes were maintained for long periods of time. Thus, clonal crops underwent in cultivation only a few recombination-and-selection cycles. In sharp contrast to sexually reproducing cultivated plants, their cultivars do not represent true breeding races but only clones, which, as a rule, are highly heterozygous and segregate widely when progeny tested. Significantly, the majority of such segregating progeny are not only economically inferior or even worthless, but they often regress toward the means found in wild populations, showing striking resemblance to the wild forms.

VII. THE PURPOSE FOR WHICH THE PLANT IS BEING GROWN

In different crops, different parts of the plant body are being used. Some are raised for their vegetative parts (tubers, leaves, stems, etc.). In others the reproductive parts (inflorescences, flowers, fruits, seeds) constitute the used products. Also the choice of the desired plant parts introduces automatically contrasting selection pressures, particularly in regard to the reproductive system of the crops involved.

When crops are grown for their seeds (or at least when they are reproduced by seed), they are kept (like their wild relatives) under constant stabilizing selection
that keeps their reproductive system intact. Grain crops provide us with the most rigid cases of such normalizing selection. Yields in these crops depend decisively on the streamlined development of flowers and fruits, normal chromosome pairing in meiosis, and full fertility. Deviants are weeded out automatically and the reproductive system is kept in balance. It is no wonder that among cultivated plants, grain crops are the most conservative in this regard. They are characterized by strictly balanced chromosome systems and show very little chromosome "problems" under domestication. With very few exceptions (such as the formation of hexaploid bread wheat), the chromosome complements in cultivars of grain crops are identical to those found in their wild progenitors.

Drastic changes in seed fertility (as well as in the chromosome system) can be tolerated when the plants are grown for their fruits but are maintained by vegetative propagation. Crops in this group (the bulk of the fruit trees) do not depend on seed fertility for their maintenance. Yet they have to keep the basic reproductive growth functions to assure the development of fruits. Moreover, growers usually prefer types in which the size and the number of stones or pips had been reduced, or seedless fleshy fruits. Several solutions for reducing seed fertility without harming fruit set evolve automatically under cultivation. They include the establishment of polyploid clones, some of them meiotically unbalanced (e.g., triploidy in some pears and in bananas), or the incorporation of mutations inducing parthenocarpy—that is, the induction of fruit development without fertilization and without seed set (e.g., bananas, fig, some pears).

Crops grown for their vegetative parts and maintained by vegetative propagation exhibit the most drastic disruption of their reproductive system and the most variable and bizarre chromosomal situations among cultivated plants. Because such crops are clonally propagated, the conscious selection exerted on them by the growers to increase the output of the desired vegetative part is rarely counterbalanced by normalizing selection to retain sexual reproductive functions. Tropical root and tuber crops provide us with outstanding examples for this development under domestication. Cultivated clones of cassava, yam, sweet potato, or garlic frequently show drastic reduction in flowering. In some, flowering ceases altogether, or almost altogether. When flowers develop they are frequently sterile. Also chromosomally many of these crops are highly polyploid or variable aneuploid chromosome numbers. Clones may contain 3x, 5x, or even higher meiotically unbalanced chromosome complements. Thus in the yams, Dioscorea alata shows all chromosome levels between 3x to 8x, whereas in D. esculenta, 4x, 6x, 9x, and 10x forms are known. Sugarcanes confront us with even more complex chromosome pictures. Cultivated clones in this crop are all highly polyploid and frequently aneuploid. Modern cultivars range from 2n = 100 to 2n = 125 chromosomes. Older cultivars vary from 2n = 80 to 2n = 124.

VIII. THE IMPACT OF SOWING AND REAPING

Traditional grain agriculture is based on sowing the seeds of the crop in a tilled field, reaping the reproductive parts of the mature plants, and threshing out the grains. The introduction of grain plants into such a farming practice mutated, automatically, selection toward the following changes, setting them apart from their wild counterparts.

1. Most conspicuous is the unconscious selection for mutants in which the mature seed is retained on the mother plant (i.e., for the breakdown of the wild mode of seed dissemination). In cereals this implies a shift from shattering spikes or panicles (in wild forms) to nonshattering ones (in plants under domestication). In pulses it usually means the prevention of the pod from dehiscing and from shedding the seeds. In wild wheat, wild barley, or wild maize, the seed dispersal unit comprises a single internode of the ear. Full disarticulation of the ear, at each segment, is thus an essential element for wild type dispersal, and plants in wild populations are constantly selected for quick shattering of their mature spikes. In contrast, the introduction of planting and harvesting brings about automatic, unconscious selection in exactly the opposite direction. Under the new system a sizable proportion of seed produced by brittle plants will shatter and would not be included in the harvest, whereas all grains produced by nonshattering mutants "wait on the stalks" to be reaped by the grower. Under cultivation, nonshattering individuals have therefore a much better chance to contribute their seed to the subsequent sowing. To summarize, nonbrittle mutants that were totally disadvantaged under wild conditions became highly successful under the new system. Thus, when wild cereals are introduced into the system of sowing and reaping, one should expect selection for nonbrittle forms whether or not the cultivator is aware of this trait. Furthermore, the incorpora-
tion of nonbrittle mutants makes the crops fully dependent on humans, as nonshattering plants lose their seed dispersal ability and can no longer survive under wild conditions. For this reason, the presence of nonshattering remains of grain crops in archaeological contexts provide critical indication that these plants were under cultivation. Finally, both theoretical considerations and experimental evidence seem to suggest that at least in wheats and barley, the establishment of nonshattering mutants under the system of sowing and reaping was very likely a fast process. The shift could have been accomplished in the course of several scores of generations.

2. A second major outcome of introducing wild grain plants into this regime of cultivation is the breakdown of the wild mode of their seed germination. Most wild plants, especially annuals, depend for their survival on regulation of their germination in space and time. A common and vital adaptation is a delay of germination and its spread over two or more years. Again, under the system of sowing and reaping such inhibition of germination is automatically selected against. Most grain crops have lost their wild-type germination inhibition patterns. Their seeds germinate fully whenever the farmer plants them.

3. Several other traits characterize cultivated grain crops and are part of the domestication syndrome under sowing and reaping conditions. Because of a rather dense stand in the cultivated field there is a stress to develop forms with erect habit and to reduce the growth of side tillers or branches. Because of the mode of harvest there is a selection for synchronous ripening. In cases of biennial or perennial wild stocks, there is an automatic selection for the shift to annuality. Because the seeds stay protected in the granary, thick shells are selected against. Finally because tilling increases soil fertility there is also a pressure to increase the number of fertile flowers in the reproductive parts of the crops.

IX. APPENDIX I: CROPS OF VARIOUS REGIONS

This appendix lists the native crops of the various traditional agricultural regions of the world (see Section II). For illustrations and short notes on the various food crops, consult Vaughan and Geissler (1997). The important crops of the world and their evolution are surveyed in Smartt and Simmonds (1995).

SOUTHWEST ASIA, MEDITERRANEAN BASIN, AND TEMPERATE EUROPE

Cereals
- Emmer and durum-type wheats *Triticum turgidum*
- Einkorn wheat *Triticum monococcum*
- Bread wheat *Triticum aestivum*
- Barley *Hordeum vulgare*
- Rye *Secale cereale*
- Common oat *Avena sativa*

Pulses
- Lentil *Lens culinaris*
- Pea *Pisum sativum*
- Chickpea *Cicer arietinum*
- Faba bean (bread bean) *Vicia faba*
- Oil or Fiber
  - Flax *Linum usitatissimum*
- Oil seed turnip *Brassica rapa*

Fruits and Nuts
- Olive *Olea europaea*
- Grapevine *Vitis vinifera*
- Fig *Ficus carica*
- Date palm *Phoenix dactylifera*
- Apple *Malus pumila*
- Pear *Pyrus communis*
- European plum *Prunus domestica*
- Sweet cherry *Prunus avium*
- Almond *Amygdalus communis*
- Walnut *Juglans regia*

Vegetables and Spices
- Melon *Cucumis melo*
- Watermelon *Citrullus lanatus*
- Onion *Allium cepa*
- Garlic *Allium sativum*
- Leek *Allium porrum*
- Lettuce *Lactuca sativa*
- Beet *Beta vulgaris*
- Turnip *Brassica rapa*
- Cabbage *Brassica oleracea*
- Carrot *Daucus carota*
- Celery *Apium graveolens*
- Parsley *Petroselinum sativum*
- Asparagus *Asparagus officinalis*
- Cumin *Cuminum cyminum*
- Coriander *Coriandrum sativum*
- Fenugreek *Trigonella foenum-graecum*
EAST ASIAN AGRICULTURE

Cereals and Cereal-Like Grain Crops
Rice Oryza sativa
Foxtail millet Setaria italica
Broomcorn millet Panicum miliaceum
Buckwheat Fagopyrum esculentum

Pulses
Soybean Glycine max

Oil or Fiber
Hemp Cannabis sativa

Vegetables and Spices
Pe Tsai (Peking cabbage) Brassica pekinensis
Pak-choi (Chinese cabbage) Brassica chinensis
Rakkyaya Allium chinense
Chinese chives Allium tuberosum
Chinese pickling melon varieties Cucumis melo

Fruits and Nuts
Chinese chestnut Castanea henryi
Chinese white pear Pyrus bretschneideri
Chinese sand pear Pyrus pyrifolia
Loquat Eriobotrya japonica
Oriental persimmon Diospyros kaki
Litchi Litchi chinensis
Apricot Prunus armeniaca
Peach Prunus persica

Corms and Tubers
Chinese varieties of turnip Brassica rapa
Chinese yam Dioscorea esculenta
Lotus Nelumbium nucifera

Stimulants
Tea Camelia sinensis

SOUTHEAST ASIAN AGRICULTURE

Pulses
Sword bean Canavalia gladiata
Mung bean Vigna radiata
Black gram Vigna mungo
Rice bean Vigna caracata

Oil or Fiber
Sesame Sesamum indicum
Tree cotton Gossypium arboreum
Coconut Cocos nucifera
Jute Corchorus capsularis

FRUITS AND NUTS
Banana: cultivated derivatives of Musa acuminata and M. balbisiana

Vegetables and Spices
Cucumber Cucumis sativus
Eggplant Solanum melongena
Black pepper Piper nigrum
Cardamom Elettaria cardamomum
Turmeric Curcuma longa
Nutmeg Myristica fragrans
Cloves Syzygium aromaticum
Ginger Zingiber officinale

Corms and Tubers

GLOSSARY

carrying capacity Usually defined as the average maximum number of individuals of a given species that can occupy a particular habitat without permanently impairing the productive capacity of that habitat (see also human load).

competitive exclusion The displacement of one species from its habitat or ecological niche by another. When humans appropriate other species' "ecological space," it often leads to the local or even global extinction of the nonhuman organism.

ecological deficit An ecological deficit exists when the "load" (see human load) imposed by a given human population on its own territory or habitat (e.g., region, country) exceeds the productive capacity of that habitat. In these circumstances, if it wishes to avoid permanent damage to its local ecosystems, the population must use some biophysical goods and services imported from elsewhere (or, alternatively, lower its material standards).

human load The total "human load" imposed on the "environment" by a specified population is the product of population size times average per capita resource consumption and waste production. The concept of "load" recognizes that human carrying capacity is a function not only of population size but also of aggregate material and energy throughput. Thus, the human carrying capacity of a defined habitat is its maximum sustainability supportive load.

overshoot A population is in overshoot when it exceeds available carrying capacity. It may survive temporarily but will eventually crash as it depletes vital natural capital (resource) stocks. A population in overshoot may permanently impair the long-term productive potential of its habitat, reducing future carrying capacity.

patch disturbance The measurable habitat and ecosystem modification caused by large animals, including humans, as they forage for food or other resources. Patch disturbance is most pronounced near the den site, temporary camp, or other central place within the overall home range of the individual or group.
sustainability gap. The global ecological deficit—that is, the difference between any excessive human load on the ecosphere and the long-term carrying (or load-bearing) capacity of the planet.

ECOLOGICAL FOOTPRINT ANALYSIS is a quantitative tool that represents the ecological load imposed on the earth by humans in spatial terms. Thus, the ecological footprint of a defined population is the total area of land and water ecosystems required to produce the resources that the population consumes, and to assimilate the wastes that the population generates, wherever on earth the land/water are located. Ecofootprinting can be used to assess the ecosystem area effectively "appropriated" in support of any specified human population or economic activity. We can then compare this to available productive area (i.e., load-bearing capacity). The size and nature of the human ecological footprint is relevant to biodiversity conservation because energy and material resources extracted from nature to serve human purposes are irreversibly unavailable to other species. The larger the human footprint, the less nonhuman biodiversity. This article describes the contemporary context for ecofootprint analysis and the theory on which it is based. It then discusses the implications of the analysis for sustainable development in general and for the future of biodiversity in particular.

I. THE CONCEPTUAL FRAMEWORK: WHY DO WE NEED ECOFOOTPRINT ANALYSIS?

A. Human Activity and Global Ecological Change

There is little disagreement among scientists that humanity has assumed a major role in changing the face of the earth. Up to one-half of the land has been directly transformed by human action; more than half of the planet's accessible fresh water is already being used by people; atmospheric carbon-dioxide has increased by 30% in the industrial era; more atmospheric nitrogen is fixed and injected into terrestrial ecosystems by humans than by all natural terrestrial processes combined; two-thirds of the world's major fisheries are fully- or overexploited; and biodiversity losses are accelerating (Lubchenco, 1998, Vitousek et al., 1997).

What is in dispute is whether any of this really matters to socioeconomic sustainability. The more pessimistic analysts see human domination of the earth and the deterioration of nature as ultimately fatal to civilization itself. Various mechanisms are invoked in coming to this conclusion. For example, because of our culture's near total dependence on liquid petroleum and the present lack of affordable substitutes, energy analyst Richard Duncan (1993) argues that the total life expectancy of western technindustrial society is less than 100 years—counting from the 1930s! Professor W. M. Hern attacks industrial culture's obsession with growth and compares humanity to a self-destructive cancer on the planet. The continuous expansion of the human enterprise apparently "exhibits all four major characteristics of a malignant process: rapid uncontrolled growth; invasion and destruction of adjacent tissues (ecosystems, in this case); metastasis (colonization and urbanization, in this case); and dedifferentiation (loss of distinctiveness in individual components") (Hern, 1997).

According to geographers J. W. Smith and G. Sauer-Thompson, environmental decay coupled with geopolitical stresses induced by resource scarcity, will inevitably cause industrial society to "self-destruct, producing massive ecological damage, social chaos, and mega-death" (Smith and Sauer-Thompson, 1998). From these perspectives, the human enterprise has already overshot global carrying capacity, is eroding future options, and will inevitably crash—there is virtually nothing we can do to prevent the collapse of global civilization.

At the other extreme, we can take comfort in the view of those scientists and economists who believe that human ingenuity will prevail. Their logic is simple. Stimulated by incipient scarcity, rising prices, and the opportunity for profit, scientists and entrepreneurs will find technological substitutes for exhaustible resources and natural processes. As energy economist R. L. Gordon explains, "the tendency to technical progress is viewed as the most critical economic law involved." And because human ingenuity has historically been remarkable at increasing living standards and warding off the pressures of resource depletion, "the immediate need for avoiding depletion is nil" (Gordon, 1994).

Perhaps the most extreme expression of this belief is revealed in the ebullient optimism of the late Julian Simon who wrote: "Technology exists now to produce in virtually inexhaustible quantities just about all the products made by nature" and "We have in our hands now ... the technology to feed, clothe, and supply energy to an ever-growing population for the next seven billion years" (Simon, 1995). Some conventional economists even argue the benefits of continuous population growth on grounds that "additional people can create more resources than they use up, thanks to technologi-
cal improvements" (Block, 1990). Clearly, from the techno-optimists' perspective, there are no practical limits at all on human carrying capacity—we don't need to do anything to sustain global civilization but stay our present, increasingly market-driven, global development course.

With such diametrically opposing assessments of the human prospect, both starting from present circumstances and held with equal conviction, it is little wonder that ordinary citizens and policy makers alike are confused about global ecological change and what—if anything—to do about it. This chapter assesses the overall sustainability conundrum using ecological footprint analysis and links the general problem to the specific issue of biodiversity conservation. First, however, we examine the origins of the ongoing perceptual conflict.

B. Dueling Paradigms

Many of the conflicting views about "sustainable development" can be traced to differing fundamental beliefs, values, and assumptions about the nature of reality, particularly humankind-environment relationships. Different societies and interest groups have different preanalytic visions (or worldviews or paradigms), which shape how they interpret any set of facts or circumstances.

Remarkably, people are often unaware that they possess a particular worldview—each person acquires his or her culturally specific paradigm unconsciously, simply by living and growing up in a particular sociocultural milieu. We may therefore be unconscious of the subtle ways in which the prevailing worldview shapes our approach to critical issues or that there may be more viable alternatives. When we think that "the world is flat" was once accepted as self-evident truth, it raises the unsettling possibility that much of our present cultural worldview consists largely of shared illusions.

The dominant social paradigm in western (and increasingly global) technocultural culture can be characterized as the "expansionist" or "cornucopian" worldview. As we have already seen, its adherents believe that humankind has achieved mastery over the natural world and that technology will be able to compensate for the depletion of natural resources and the loss of life-support services.

The economics of expansionism is the neoclassical (neoliberal) economics that has come to dominate geopolitics in the past 20 years. Neoclassical models generally represent the economy as a self-regulating and self-sustaining mechanical system whose productivity and growth are not seriously constrained by nature. In effect, conventional economics treats the economy as separate from, and more or less independent of, "the environment." People can therefore be treated solely as economic agents.

By contrast, ecologists, environmentalists, and many pessimists profess an ecological or steady-state worldview. From this perspective, the economy, far from being a separate system, is seen as an inextricably integrated, completely contained, and wholly dependent growing subsystem of a non-growing ecosystem. People are not only economic agents but also ecological agents.

The ecological perspective recognizes that the so-called environmental crisis is really a human ecological crisis. The distinction is by no means trivial. The former term externalizes the problem, effectively blaming it on a defective environment, which then needs to be fixed. By contrast, the latter term traces the problem to its source—the nature and behavior of people themselves—and suggests that it is the latter that need "fixing." This is the starting point for ecological footprint analysis.

C. Human Ecology/Economy and the "Second Law"

If humans are ecological entities then human activity is governed by natural laws. In particular, economic production requires continuous, irreversible energy and material transformations, and these transformations are ultimately governed by the second law of thermodynamics. This fundamental law is ignored by conventional economic models.

In its simplest form, the second law states that any isolated system will tend toward equilibrium; alternatively, the "entropy" of any isolated system always increases. Available energy spontaneously dissipates, concentrations disperse, gradients disappear. An isolated system thus becomes increasingly unstructured in a inexorable slide toward thermodynamic equilibrium. This is a state of maximum entropy in which there is no structure and nothing can happen.

The second law was originally formulated for simple isolated systems close to equilibrium. We now recognize, however, that even complex open systems are subject to the forces of entropic decay. Any differentiated far-from-equilibrium system has a natural tendency to erode and unravel.

But not all complex systems do disintegrate in this way. Many biophysical systems, from individual lizards to the entire ecosphere, actually gain in organizational
complexity and mass over time (i.e., they increase their distance from equilibrium). This seemingly paradoxical behavior can readily be reconciled with the second law. Biophysical systems exist in loose, nested hierarchies, each component system being contained by the next level up and itself comprising a chain of linked subsystems at lower levels. Living systems can therefore import available energy and material (essergy) from their host environments and use it to maintain their internal integrity against entropic decay and to grow. They also export the resultant waste (entropy) back into their hosts. In effect, modern formulations of the second law posit that all highly ordered systems develop and grow (increase their internal order) at the cost of destroying order at higher levels in the systems hierarchy. Because such systems maintain themselves by continuously degrading and dissipating available energy and matter, they are called "dissipative structures."

Now, the human economy is clearly one such highly ordered, complex, dissipative structure. Both our biological and our industrial metabolisms require enormous inputs of high-grade energy and material resources from the rest of the ecosphere for their maintenance and growth. Indeed, from the ecological perspective, humans are strictly secondary producers—all production by the human enterprise, from the increase in population to the accumulation of manufactured capital, requires the consumption of a much larger quantity of energy and material first produced by nature (although we can sometimes increase the amount of incoming solar energy captured by photosynthesis through irrigation, or by building terraces for agriculture, for example).

Moreover, recall that within the global hierarchy, the economy is a dependent subsystem of the ecosphere. In effect, the expanding human enterprise is positioned to consume the ecosphere from within. Beyond certain limits, continuous population and material economic growth is, therefore, inherently self-destructive. This reality suggests a necessary second law condition for sustainability: material consumption and waste production by the economy must be no greater than the resource production and waste assimilation capacity of the ecosphere.

D. Homo Sapiens: The Archetypal Patch Disturbance Species

Evidence to support the ecological view has accumulated throughout history. Even preagricultural humans had significant effects on local ecosystems' structure and function and on the biodiversity of their habitats. This was the inevitable consequence of the second law combined with two additional facts of human biology: human beings are large animals with correspondingly large individual energy and material requirements (i.e., we are big consumers), and humans are social beings who live in extended groups. Consequently, whenever human hunter-gatherers invaded a previously "stable" ecosystem, their material demands would significantly alter established energy and material pathways, benefiting some nonhuman species and harming others. People invariably perturb or disturb the systems of which they are a part.

Perhaps the most dramatic evidence is the permanent systemic changes that occur when humans first invade and settle a new habitat. Consider biodiversity loss. The recent paleoecological, anthropological, and archeological literature tells a convincing story of the extinctions of large mammals and birds that accompanied first contact and settlement of their habitats by human beings (Diamond, 1992; Flannery, 1994; Ponting, 1991). It seems that everywhere on earth that paleontologists have studied and that humans first reached within the past fifty thousand years, human arrival approximately coincided with massive prehistoric extinctions. In North America, South America, and Australia, about 72, 80, and 86%, respectively, of large mammal genera ultimately became extinct after human arrival. Scientists estimate that with only Stone Age technology, the Polynesians exterminated more than 2000 bird species, about 13% of the world total.

All this is to emphasize that humans are, by nature, a patch-disturbance species, a distinction we share with other large mammals ranging from beavers to elephants. Large animals, due to their size, longevity, and food and habitat requirements, tend to have substantial physical and systemic impacts on the ecosystems that sustain them. A patch-disturbance species may thus be defined as any organism that, usually by central place foraging, degrades a small "central place" greatly and disturbs a much larger area away from the central core to a lesser extent.

There is, of course, a major difference between human patch disturbance and that of other species. Because human knowledge and technology are uniquely cumulative, human patch disturbance has been intensifying since the Neolithic. It received a major boost with agriculture and became the dominant force in the ecosphere with the use of fossil fuels and the industrial revolution. (Cheap, plentiful fossil fuels have enabled humans to accelerate the exploitation of everything else.) Today, human patch disturbance is evident on a global scale in the form of such persistent negative
trends as greenhouse gas accumulation, increasing climatic variability, ozone depletion, landscape destruction, and accelerating biodiversity loss. Ultimately, the erosion of systems integrity may lead to the irreversible loss of basic life support functions.

Whatever joy one might take from the human symphony, the fact that economic growth now threatens critical biophysical systems sounds a discordant note. Global change implies that economic activity is pressing against the limits of human carrying capacity at the expense of other species. Regrettably, the concept of human carrying capacity has long been rejected by mainstream analysts, but for reasons explained below, it is the organizing principle of ecological footprinting.

II. REVISITING HUMAN CARRYING CAPACITY: THE ROOTS OF ECOFOOTPRINT ANALYSIS

Ecologists who study nonhuman species generally define carrying capacity in terms of the numbers of deer, elk, or other species that a particular habitat type can support indefinitely per unit area. However, because of such factors as climatic variability and community succession, instantaneous carrying capacity is constantly changing. Carrying capacity is therefore not a particularly rigorous concept, even when applied to nonhuman species with simple stable demands on their ecosystems. It is all the more problematic when applied to humans whose demands on the environment are anything but simple and stable.

Indeed, many economists and other cornucopians argue that interregional trade alone is virtuously enough to cancel concerns about human carrying capacity. Any region or country that can trade services or surpluses of resource A for needed supplies of resource B need not be limited in numbers or economic growth by the theoretical carrying capacity of its home territory. Furthermore, if trade fails, we can always rely on human ingenuity and technology to increase carrying capacity. These are seemingly powerful arguments, and they explain how such densely populated countries as the Netherlands and the United Kingdom can remain economically vigorous despite having long exceeded their domestic carrying capacities.

But let’s examine the assumptions here. The idea that trade acts to increase local carrying capacity treats each trading region as an isolated open system. Looked at in the aggregate the situation becomes cloudier. The world as a whole is a materially closed system. Resources imported to and consumed in region A are no longer available for consumption in the exporting region B, and visa versa. Hence, the exchange may result in a one-time increase in the population of each region taken separately, but it also increases global consumption and may deplete local stocks of natural capital, thereby limiting future options. Thus, although total human load increases, there is no unambiguous increase in total load-bearing capacity.

Indeed, in some circumstances unfettered trade can lead to a permanent loss of carrying capacity. Global trade exposes pockets of scarce resources everywhere to the largest possible market. This subjects them to ever-greater exploitation pressure, often to the point of depletion or collapse. (Such is the history of trade in fisheries products, for example.) In short, instead of increasing load-bearing capacity, trade often just shuffles it around. This ensures that all countries, their economies happily expanding through trade, hit the (now shrinking) limits to growth simultaneously. Stratospheric ozone depletion is a case in point.

What about human ingenuity? The general argument here is that cumulative knowledge and technological skills enable humans to squeeze more out the environment than nature-in-the-raw can provide. This is achieved mainly by continuously increasing resource productivity and by creating substitutes for any resources that are eventually depleted. In these ways, we are able to increase the capacity of any given habitat to support humans and their activities without practical limit.

Let’s take these points one at a time. The so-called green revolution, for example, is frequently cited as a miracle of human technological prowess. High-input production agriculture has, in fact, greatly increased the short-term productivity (carrying capacity) of arable land. This has seemingly banished the threat of Malthusian famine and certainly facilitated the modern population explosion. However, this miracle was achieved largely by supplementing renewable sun, soil, and rain with nonrenewable fossil fuel, fertilizer, pesticides, and depletable groundwater at a great cost in soil degradation, biodiversity loss, widespread pollution, and falling water tables. The net effect is a swollen human population, likely in overshoot, and increasingly dependent for survival on nonrenewable artificial inputs, even as pollution mounts and natural long term load-bearing capacity is steadily eroded.

Another potential fix is our demonstrated ability to greatly increase resource productivity, to do more with less. In theory, more efficient technologies should en-
able a constant energy and material supply to support a given population at a higher material standard, or a higher population at the same material standard, thereby seeming to increase carrying capacity.

Unfortunately, real-world practice has so far betrayed theoretical promise. The steady gains in material efficiency in the post World War II period have been accompanied by both an exploding population and steadily increasing consumption. A recent study of resource flows in a selection of the world's most technologically advanced and efficient countries found that although there has been some reduction in the ratio of resource inputs per unit gross domestic product since 1975, there has also been "in most, a gradual rise in *per capita* natural resource use." The study therefore concludes that "meaningful dematerialization, in the sense of an absolute reduction in natural resource use, is not yet taking place" (WRI, 1997, p. 2). In fact, efficiency gains may actually work against conservation by lowering prices and raising incomes. This gives people more money to spend on cheaper goods and services so total throughput—human load—keeps expanding.

Finally, overconfidence in resource substitution is also problematic. It is true that human ingenuity has been markedly successful at finding replacements for simple material inputs to production. For example, optical fiber is a product of mind, not of nature, and has displaced much of the demand for copper wire. However, as ecological economist Herman Daly (1991) has emphasized, there are many more circumstances in which technology and nature are complements, not substitutes. More fish boats cannot long substitute for fewer fish; more saws and carpenters are no substitute for less lumber. Indeed, natural capital (e.g., timber, steel, aluminum) is actually a prerequisite for manufactured capital (e.g., fish boat) since the latter is made from the former. More generally, we should emphasize that the growing need for technology-based substitutes (e.g., fertilizer) is a warning signal that natural load-bearing factors (e.g., productive soil) are being permanently eroded.

In summary, confidence that expanding trade and technical wizardry have infinitely expanded human carrying capacity and banished the Malthusian specter forever is premature. Carrying capacity is still very much applicable to humans, and given present trends it is likely to become a major preoccupation of global development policy in coming decades. However, as this discussion will show, we need new approaches to the analysis of carrying capacity, methods that account for uniquely human cultural attributes, including trade and technology.

III. THE LOGIC AND STRUCTURE OF ECOLOGICAL FOOTPRINT ANALYSIS

A. Basic Concepts

Ecological footprint analysis is one such analytic method. Ecofootprinting starts from the premise that, conscious of it or not, modern human beings are integral components of the ecosystems that support them and therefore still very much dependent on "the land" (Rees, 1996; Wackernagel and Rees 1996).

The method also explicitly recognizes (a) that whether one consumes locally-produced products or trade goods, the land connection remains intact, however far removed from the point of consumption some of that land may be, and (b) that no matter how sophisticated our technology, the production/consumption process requires some land- and water-based ecosystems services. Ecofootprint analysis thus incorporates the trade and technology factors simply by inverting the standard carrying capacity ratio: rather than asking what population can be supported by a given area, ecofootprinting estimates how much area is needed to support a given population, regardless of the location of the land or the efficiency of relevant technologies.

Ecofootprinting builds on traditional trophic ecology by constructing what is, in effect, an elaborate "food-web" for the study population. This requires quantifying the material and energy flows supporting the population and identifying corresponding significant sources of resources and sinks for wastes. As we have noted, the human food-web differs significantly from those of other species. In addition to the material and energy required to satisfy the metabolic requirements of our bodies, a human food-web must also account for the needs of our industrial metabolism.

Ecofootprinting is further based on the fact that many material and energy flows (resource consumption and waste production) can be converted into land and water-area equivalents. These are the ecosystem areas required to produce the biophysical goods and services used by the study population. Thus, the ecological footprint of a specified population is the area of land and water ecosystems required to produce the resources consumed and to assimilate the wastes generated by that population on a continuous basis, wherever on earth the land/water may be located. A complete ecofootprint analysis would therefore include both the area the population "appropriates" through commodity trade and the area it needs to provide its share of certain free land-
and water-based services of nature (e.g., the carbon sink function).

The area of a given population's ecofootprint actually depends on four factors: the size of the population, the people's average material standard of living, the productivity of the land/water base, and the technological efficiency of resource harvesting, processing, and use. Regardless of how these factors interact, ecofootprinting represents critical natural capital requirements of the study population in terms of corresponding productive land and water area. We can also think of the ecological footprint as representing the extended patch (productive habitat) occupied ecologically by the study population.

It is critical to recognize that ecofootprints represent ecologically exclusive areas. The productive capacity used by one human population is not available for use by another. Although two or more human groups may share in the output of the same exporting region, the total ecosystem area appropriated is the sum of the areas required by the individual populations. In the final analysis, all human populations are in competition for the available load-bearing capacity of the earth.

### B. The Method in Brief

Population ecological footprints are generally based on final demand for goods and materially intensive services by the referent population. Thus, the first step in calculating the ecological footprint of a study population is to compile, item by item, the total annualized consumption of each significant commodity or consumer good used by that population. Data are obtained from national production and trade statistics and other sources such as United Nations statistical publications. For accuracy, consumption data should be trade-corrected. Thus the population's consumption of wheat can be represented as follows:

\[
\text{consumption}_{\text{wheat}} = \text{production}_{\text{wheat}} + \text{imports}_{\text{wheat}} - \text{exports}_{\text{wheat}}.
\]

The second step is to convert consumption of each item into the land area required to produce that item by dividing total consumption by land productivity or yield. This actually gives us the ecological footprint of the individual item. In general:

\[
a_i = c_i / y_i,
\]

where: \(a_i\) is the ecofootprint of item \(i\) in hectares, \(c_i\) is total consumption of item \(i\) in kilograms, and \(y_i\) is the yield of item \(i\) in kilograms per hectare. Thus, for wheat:

\[
a_{\text{wheat}} = c_{\text{wheat}} / y_{\text{wheat}} = \text{kg}_{\text{wheat}} / (\text{kg}_{\text{wheat}} \times \text{ha}^{-1})
\]

Next, the aggregate ecological footprint of the population, \(F_p\), is determined by summing the footprints for the \(n\) individual items:

\[
F_p = \sum_{i=1}^{n} a_i
\]

Finally, the per capita ecological footprint, \(f_c\), is obtained by dividing the total population footprint by population size, \(N\):

\[
f_c = F_p / N
\]

For some wastes (such as carbon dioxide emissions) or nutrients (such as phosphates and nitrates), it is also possible to calculate the land (or aquatic) ecosystem area required for sustainable assimilation and recycling. In these cases, the assimilation rate per hectare and year is substituted for \(y\) (yield) noted earlier. Box 1 illustrates a basic ecofootprint calculation (aggregate grain consumption in Canada).

We calculate ecofootprint estimates using standard spreadsheet software. Spreadsheets for recent ecofootprint calculations feature up to 132 rows (consumption items) and 15 columns (yield, production, imports, exports, apparent consumption, etc.), with the last column giving the ecofootprint components attributable to each consumption item (see Wackernagel et al., 1999).

Double-counting is avoided whenever identified. For example, if in the analysis of a particular city's ecological

---

**Box 1**

Sample Calculation: The Ecological Footprint of Grain Consumption in Canada (1993 data)

- Total population (N): 28,817,000
- Average yield (y): 2744 kg × ha⁻¹ (2.74 tonnes × ha⁻¹)
- Domestic production (p): 51,416,000 tonnes (t)
- Imports (i): 499,100 t
- Exports (e): 26,428,400 t
- Domestic consumption (c = p + i - e): 25,486,700 t
- Ecofootprint of grain consumption by Canadians \((a = c \times y^{-1})\): 9,288,200 ha arable land
- Per capita ecofootprint attributable to grain consumption \((f = a \times N^{-1})\): .32 ha arable land.
footprint one wishes to account for food-related nutrient assimilation but finds that the city's domestic wastes are composted and spread on adjacent agricultural or commercial forest land, then only the agricultural and forest products footprint components should be compiled in the total footprint analysis. Similarly, some consumer products such as leather goods are the by-product of another industry (in this case, beef production). In such cases, one would generally count only the primary land requirements (the grazing and grain lands required for feeding cattle). (For some purposes, of course, it may be of interest to apportion the land among the various products associated with the primary use.)

To estimate typical population ecological footprints (e.g., for whole regions or countries), we usually start with world average land productivities or yields. This greatly simplifies calculations because we do not have to trace all the sources of trade goods and waste sinks or determine the productivity and assimilative capacities of the corresponding production/assimilation areas. As important, using a common base yield facilitates comparison among countries and comparisons of individual countries with global totals. This shortcut is also becoming increasingly realistic for many countries that are heavily dependent on trade flows of commodities from various sources. (Note that the global ecofootprint estimate produced by this method would be the same as the global total estimate that would result if actual yields were used for all items and countries.)

For some kinds of analyses, of course, it might be necessary or useful to base the ecofootprint calculation on actual land/water yields where sources are known and data are available. Also, to compare a country's or region's ecofootprint with the productive or load-bearing capacity of its own domestic territory, we must know the actual productivity of various domestic land categories (cropland, pasture land, forests, carbon sinks, etc.) in order to calculate that country's ecological deficit (or surplus).

For example, if a given country's cropland is three times as productive as world average cropland, we would multiply the area of that country's cropland by a yield factor of three before comparing it to (i.e., subtracting it from) the calculated cropland footprint, as each domestic hectare is the yield equivalent of three global average hectares. This gives a more accurate estimate of the de facto ecological deficit (or surplus) in cropland. Note, however, that if the higher productivity of the domestic land is the result of intensive fertilizer and pesticide use, the apparent reduction in the ecological deficit due to higher cropland productivity will be at least partially canceled out by the increase in the ecological footprint attributable to the use of agricultural chemicals (fossil fuels are an important feedstock in the manufacture of these inputs).

In general, we err on the side of caution in making ecofootprint estimates. For example, if there is dispute over, or several estimates of, land productivity, we use the higher estimate (reduces footprint size). Most ecological footprint calculations are therefore likely to under- rather than overestimate.

IV. HUMAN ECOLOGICAL FOOTPRINTS: IMPLICATIONS FOR GLOBAL SUSTAINABILITY

So, how big are our ecological footprints? Most citizens of industrialized high-income countries feel so distanced from nature that it has simply never occurred to them to ask, "How much of the earth's surface is dedicated to supporting just me in the style to which I have become accustomed?" They are generally shocked to learn that average residents of North America, Europe, Japan, and Australia require the biophysical output of 5 to 10 hectares (12-25 acres) of biophysically productive land and water each to support their consumer lifestyles (Rees, 1996; Wackernagel and Rees, 1996; Wackernagel et al., 1999). Such large ecofootprints are also exerted by members of wealthy urban elites throughout the developing world.

A. The Functional Footprints of Cities

These findings should alter our perceptions about many things. To begin, they should change how we think about cities and urban land. Almost 30 years ago, American ecologist Eugene Odum wrote, "Great cities are planned and grew without any regard for the fact that they are parasites on the countryside which must somehow supply food, water, air, and degrade huge quantities of waste" (Odum, 1971). Ecofootprinting enables us to quantify the extent of this urban "parasitism." For example, in 1996 Canada's largest city, metropolitan Toronto, had a population of approximately 2,385,000 living in an area of 630 km². Assuming they are typical Canadians, Toronto's citizens had an average ecological footprint of about 7.7 hectares (19 acres). Thus the ecological footprint of metro Toronto was 183,650 km², or about 290 times the size of its then political area.
Most of the city's supportive ecosystems are located at great distance from the people they sustain; indeed, they are scattered all over the planet.

This situation is characteristic of high-income cities. In a particularly comprehensive analysis, Folke et al. (1997) estimated that the 29 largest cities of Baluc Europe appropriate for their resource consumption and waste assimilation an area of forest, agricultural, marine, and wetland ecosystems 565 to 1130 times larger than the areas of the cities themselves. A study for the International Institute for Economy and Development in London shows that the biophysical demands of that city alone appropriate an area scattered around the world equivalent to all the ecologically productive land in the United Kingdom.

Such findings have important implications for both urban development and rural sustainability in the 21st century. Some people interpret the global migration of people from the countryside to the city as implying that modern humans are abandoning the countryside and becoming less dependent on the land. This is illusion. The reality is that productive croplands, pasture lands, and forests everywhere are being used more intensely than ever to sustain the world's burgeoning urban populations. The human occupants of cities may think of the latter as their principal habitat, but cities per se represent only a tiny fraction of the total human ecosystem.

There is, of course, a certain mutualism between the city and the countryside. Cities need the resources of rural areas and rural areas benefit from urban markets and technology transfers from cities. However, while rural areas could survive without cities, the dependence of cities on rural environments is absolute. In short, there can be no urban sustainability without rural sustainability. In this light, we might even want to reconsider what we think of as urban-dominated land—in a whole-systems ecological sense, the great plains of North America, one of the world's major breadbaskets, are an essential component of the increasingly urban global human ecosystem.

According to United Nations' projections, there will be 27 cities with populations exceeding 10 million by 2015 (up from only 1 in 1950). Forty-four more cities will have populations of 5 to 10 million by the same year. This should trigger at least a cautionary alarm. The world's megacities—all cities for that matter—are dependent on a vastly larger area of productive lands outside their boundaries and political control. But just how secure can any urban population be if the lands represented by its ecological footprint are under threat from ecological change or geopolitical uncertainty?

B. Ecofootprints, Global Development, and Social Equity

It is not just cities that overshoot the productive capacity of ecosystems within their political domain. Most high-income countries have an ecological footprint several times larger than their national territories. In effect, they are running massive ecological deficits with the rest of the world. As a result of continuous population growth, rising material demand, and expanding trade, wealthy consumers in particular have ecological footprints that treat the entire planet as their common patch.

In fact, several ecofootprint studies suggest that humanity is now running a global ecological deficit of up to 30% and is accumulating a nonpayable ecological debt. Even at current average levels of economic production and consumption, the human load already exceeds the long-term carrying capacity of the earth. The direct empirical evidence (e.g., ozone depletion, climate change, fisheries collapse) is becoming the stuff of daily newspaper headlines.

This means that contrary to the assumptions of prevailing international development models, so-called first-world material lifestyles are not sustainably extendible to the entire world population using prevailing technology. Although wealthy consumers require the goods and life support services of 5 to 10 hectares of productive land and water there are only about two hectares of such land per person on earth. Meanwhile, the great majority of humankind is understandably not satisfied with its present material lot and is determined to improve it. (Despite the recent industrial revolution in China, the ecological footprint of the average Chinese is less than 1.5 hectares and Bangladeshis get by on only half an hectare.) The problem is, to support all six billion members of the human family at the average North American material standard would require about three additional earthlike planets (and this does not account for the needs of the three billion more people to come by the middle of the 21st century).

If we are at or beyond the human load-bearing capacity of the planet, then the only way additional population or material growth can be sustained, without ravaging biodiversity and ultimately destroying the ecological basis of human life, is through massive cutbacks in resource consumption by the presently wealthy. In theory this could be achieved through a tightly managed new efficiency revolution (doing much more with less) in combination with an absolute reduction in material demand (i.e., a shift to simpler lifestyles).

Other carrying capacity studies have reached similar
conclusions. Using data on current waste discharge rates and the assimilative capacity of biophysical systems, the Sustainable Europe Campaign has estimated that sustainability requires an approximately 50% reduction in the material throughput of the global economy in coming decades. However, in order to create the necessary environmental space for developing countries to claim their fair share of global carrying capacity, developed countries must reduce their consumption of various nonrenewable resources by between 88 and 94% (Carley and Spapens, 1999).

This might seem to be an extreme conclusion and impossible goal. However, the United Nations Environment Program's “Global Environment Outlook 2000” report also argues the need for a tenfold reduction in resource consumption by high-income countries. Even the Geneva-based world Business Council for Sustainable Development acknowledged as early as 1993 that “industrialized world reductions in material throughput, energy use, and environmental degradation of over 90% will be required by 2040 to meet the needs of a growing world population fairly within the planet's ecological means” (BCSD, 1993).

If so-called postindustrial society fails to meet this challenge, the anticipated doubling and doubling again of the human material demand in the next half-century will be disastrous for conservation efforts. As explained next, the expanding human ecological footprint inevitably reduces the ecological space available for other species.

V. HUMAN ECOLOGICAL FOOTPRINTS AND THE BIODIVERSITY CRISIS

Human beings are uniquely successful among large mammals in mastering the variety of environments on earth and in expanding both numerically and spatially over the globe. Our capacity to extend continuously our ecological footprint is attributable to several species-specific qualities of which perhaps three stand out.

First, humans have a remarkably variable diet—we have wide-ranging omnivorous tastes and if we cannot consume something directly (such as grass), we domesticate an animal that will and then eat the animal. This means that humans may well possess the broadest food niche of any vertebrate on the planet. Second, humans are as behaviorally adaptable as they are catholic in their diets. Together, these two factors make virtually any terrestrial ecosystem on earth accessible to Homo sapiens. No other species has managed successfully to colonize and dominate virtually all major terrestrial ecosystem types, from grasslands and forests to deserts and tundra, on all the world’s significant land masses. Finally, we are creatures of language, culture, and cumulative learning. Technological advance has enabled humans continuously to increase the intensity of resource exploitation and to extend their ecological footprint into virtually all remaining productive habitats on the planet. For example, thanks to electronic fish-finding devices and ruthlessly effective fishing gear, humans have actually become the functionally dominant marine mammal. By the mid-1990s, the world's fishers were appropriating the equivalent of 25 to 35% of the product of net photosynthesis from the 10% of the oceans that produces 96% of the catchable fish.

We previously noted that human ascendance has historically been achieved at the expense of other species. People's material demands, culminating in today's global consumer society, have steadily appropriated an increasingly disproportionate share of the planet's finite productive and sink capacities. The recent human dominance of ocean ecosystems provides several examples of the resulting biodiversity loss.

To begin, some modern fish-harvesting techniques have devastating impacts on the physical and biological structure of marine habitats, thereby reducing the productivity, diversity, and abundance of both target and no-target species. Various surveys reveal that fishers now drag heavy trawls over all the oceans' continental shelves at least once every two years and some areas are hit several times in a season. In heavily fished regions of the North Sea, trawlers make up to seven passes annually with nets and chains weighing up to five tons. The total area affected by trawls is 150 times larger than the area of forest clear cut globally each year.

Many fish-stock depletions and the destruction of benthic communities are the direct result of the increasing intensity of commercial fishing. However, other systemic problems stem from the fact that expanding the human marine ecofootprint inevitably diverts an ever greater proportion of the finite energy budget of the sea away from other marine predators, including various fish, birds, and mammals.

A particularly telling example of the resultant domino effect can be traced to a tripling of the commercial catch of Alaska pollock since 1986. The reduced availability of pollock apparently precipitated a decline in populations of Steller's sea lions and seals, which feed on pollock. By the late 1990s, sea lion populations in the Gulf of Alaska had fallen by 80 to 90%, in turn depriving local orca (killer whale) populations of their normal primary food source. With the collapse of sea
lions and seals, the orcas turned to eating sea otters—smaller, less fatty animals—whose populations have also now also fallen by 80 to 90% since 1990. But the systemic shifts and biodiversity losses do not end there. Sea otters seem to be a keystone species in the shallow marine kelp forests that constitute their preferred habitat. Among the otters’ major prey are sea urchins, which, in turn, graze on kelp. As the otter population declined there was an explosion of sea urchins, leading to the destruction of the kelp beds by overgrazing. So it is that human overfishing for pollack precipitated the collapse of one of the most productive inshore-marine ecosystems in the North Pacific, as so-called sea urchin barrens spread along the coast of Alaska and the adjacent Aleutian Island chain. (Dramatic as this example might seem in its own right, it is only just the final chapter of a longer book. Direct human overharvesting of sea otters for their pelts, beginning in the 19th century, had already long since decimated the kelp forests, which previously characterized much of the Pacific coast of North America from California north.)

Some popular accounts of this phenomenon have emphasized the role of orcas in switching prey from seals to otters. Certainly this was an important link in the chain of events, but the structural change mainly responsible for precipitating the collapse of the near-shore ecosystem was the displacement by humans of sea lions, seals, and ultimately orcas from their ecological niches among the top carnivores in the offshore ecosystem. As humans replaced seals in the food-web, the killer whales were forced to switch to sea otters, a much inferior food source.

This example underscores how, whether conscious of it or not, Homo sapiens have become the ecologically dominant marine mammal. But the main point to take away is that uncontrolled increases in human appropriations of bioproducitivity inevitably result in the rerouting of energy and material flows through the affected ecosystems—marine or terrestrial—with consequent and potentially permanent changes in ecosystem structure and function.

We now recognize that several mechanisms are at work as humans extend their ecological footprints. People

1. Passively displace other species from their food niches or appropriate their habitats. (Commercial fishing displaced sea lions, seals, and orcas on the northwest Alaska coast; agriculture pushed bison from the Great Plains of North America; clearing for crops and grazing has destroyed thousands of species in former tropical forests.)

2. Actively eliminate nonhuman competitors—other species that compete with us for “our” food. (We shoot wolves that hunt ungulates, and seals that eat commercially valuable fish; we poison insects that would devour our crops.)

3. Deplete both self-producing and nonrenewable “natural capital” stocks. (Humans overexploit many wild prey populations from hios to fish; destroy whole ecosystems such as forests; and deplete vital assets such as groundwater, soils, and fossil fuels.)

These processes are all consumption-related. The first two are forms of competitive exclusion. Technological “man” is simply more effective than other organisms at appropriating nature’s bounty for his or her own use. Because energy and material flows used by people are irreversibly unavailable for other species, the latter decline, even to extinction, at least locally.

The third mechanism, stock depletion, is the product of many things, including confidence in technological substitution, blind ignorance, material greed, sheer desperation, and the relentless working of the so-called common property problem on an overcrowded planet. Sometimes it is even the result of willful disregard on the part of those who give no moral standing to other creatures or who simply don’t care about the state or fate of the world.

Economic globalization, the sanctioning of greed, the rise of consumerism, and the spread of energy-intensive technologies have intensified all these processes. Overharvesting and habitat destruction are driving what some analysts refer to as the “sixth extinction.” According to Biologist E. O. Wilson, the earth is now experiencing the greatest extinction episode since the natural catastrophes at the end of the Paleozoic and Mesozoic eras. The current species extinction rate is 100 to 1000 times prehuman levels inferred from the fossil and paleontological record. A quarter of bird species have already been extinguished by people and fully a quarter of the 4400 mammal species living today are on a path of decline that, if not reversed, is also likely to end in extinction.

The contemporary human ecofootprint is also characterized by massive increases in waste production. Not surprisingly, the resultant pollution is adding to the toll on biodiversity. A poignant example is the phenomenon of “coral bleaching,” which has been in the news since the mid-1980s. This effect is produced when the animal component of coral organisms—corals are a
The mutualistic union of animal polyps and plant (algae) cells—expel their algal cohabitants as a result of thermal or other stress. The loss of algae leaves the coral pale and washed out (bleached) and unable to grow or reproduce. In the exceptionally warm spring and summer of 1998, coral bleaching associated with a one Celsius degree increase in ocean temperature extended across the tropics, including, for the first time, the Indian Ocean. Reports indicate that 70 to 90% of corals in the Indian Ocean basin appear to have been affected.

Some scientists have referred to the bleaching and die-back of corals as an unprecedented ecological disaster. Coral reefs are among the most diverse and productive ecosystems on the planet. Numerous fisheries, particularly locally important food fisheries, are sustained by the productivity of corals. What economic and social costs would be incurred if the decline of corals and associated reef habitats continues unabated? How will we measure the ultimate consequences of the sheer loss of biodiversity? Most important, what does the apparent spread of the problem say about the state of the earth in general and the marine environment in particular?

These are important questions, but the main point is that to the extent that coral bleaching is caused by human-induced global warming, it is the indirect result of greenhouse gas accumulation in the atmosphere. (The earth’s carbon sinks are overwhelming.) The attendant biodiversity loss is therefore the distal product of the industrial world’s addictive dependence on fossil fuels and our ever-expanding industrial metabolism. Regrettably, if the climate change/global warming hypothesis proves to be correct, coral bleaching will not soon be reversed by any political action feasible under the prevailing global development model.

All these examples underscore the inverse relationship between growth of the human ecological footprint and biodiversity (the competitive exclusion principle at work). Unfortunately, at present, ecofootprint analysis does not directly track biodiversity losses. However, the negative correlation is most directly associated with the conversion of wildlands to agriculture, intensive (including plantation) forestry, and various forms of habitat fragmentation. Many of these conversions are measurable. It may therefore eventually be possible, using the historical record and principles of biogeography, to link some index of biodiversity loss to the growth of population ecofootprints.

Whether or not this relationship can be rigorously defined, the basic point stands. To the extent that further human population and material growth requires the clearing of forests and the intensification of agriculture, and is accompanied by urban sprawl and pollution, it necessarily means less ecological space to sustain nonhuman species and ecosystems. Biodiversity loss is thus virtually certain to accelerate under the prevailing global development scenario.

VI. ASSESSING THE ECOLOGICAL FOOTPRINT APPROACH

A. Conceptual and Methodological Strengths

Ecofootprint analysis brings several methodological strengths to bear in assessing the state of the world. First, it is compatible with various concepts developed by other analysts to address human ecological problems. For example, the ecological footprint concept

- incorporates and extends George Borgstrom’s 1960s notion of “ghost acreage,” referring to the extra-territorial food lands required to support densely populated regions and countries.
- corresponds closely to Paul Ehrlich’s and John Holdren’s 1970s definition of human impact on the environment: I = PAT, where I is impact, P is population, A is affluence, and T is technology. The population ecological footprint (E_P) corresponds to impact (I) in the latter formulation and is itself a function of population size and consumption. However, because consumption is a function of income (affluence) and the state of technology, I, like E_P, is a function of population and consumption. From this perspective, E_P is an area-based analogue of I.
- provides one measure of human load defined by Catton (1980) as a function of population size and average individual impact (consumption again). The larger the footprint, the greater the load. (Catton defined carrying capacity as the “maximum persistently sustainable load.”)
- is conceptually related to the embodied energy (energy) analyses of ecologist Howard Odum and recognizes the importance of the second law of thermodynamics to human affairs as stressed by ecological economists Nicholas Georgescu-Roegen and Herman Daly. Indeed, the area represented by the ecological footprint can be conceived as the photosynthetic surface (solar collector) needed to replace the free energy (essergy or negentropy) dissipated by humans and their industrial metabolism.
However, for all its technical compatibility, perhaps the major strength of the eco-footprint concept is conceptual simplicity and intuitive appeal. First, the ‘footprint’ metaphor seems particularly effective in communicating the idea that we each have an impact on the Earth for which we are responsible through consumption choices. Second, ecofootprinting consolidates real data on a variety of energy and material flows into a single concrete variable, land area. Land is a particularly powerful indicator because it too is readily understood by ordinary people.

Because the supply of land is finite at any scale, ecofootprint analysis provides a measure of human demand (load) for comparison with supply (load bearing capacity) at all geographic levels from local to global. Such comparisons suggest several secondary indices of (un)sustainability that can be used to stimulate discussion of sustainability options or in establishing measurable policy targets. For example, if we are running a local or regional ecological deficit, the question becomes: Is this a major problem and, if so, what must be done to reduce it? (Note that humanity’s total ecological deficit, the sustainability gap, may ultimately be more important than any fiscal deficit yet is totally ignored in most national accounting systems and international developmental planning.)

To be sure, it is unlikely ecofootprint analysis will ever cope satisfactorily with various toxic waste discharges into the ambient environment. The biological effects of chronic low-level chemical contamination (e.g., carcinogens), for example, do not readily translate into an appropriated land area. However, this may not be as problematic as it seems. Environmental and ecological economists already agree that society should have zero tolerance for highly toxic chemical wastes and radioactive substances for which the ecosphere has no measurable assimilative capacity. Such substances should simply be banned or phased out (as in the case of chlorinated pesticides and ozone-depleting CFCs).

In any event, no single index can be expected to represent all ecological impacts and this limitation does not invalidate what ecofootprinting does reveal. Rather, it suggests that ecofootprint calculations are almost certainly underestimates of actual ecosystem appropriations and that methodological improvements and extensions may well result in considerably larger ecofootprints. As it is, ecofootprinting already provides unambiguous results and suggests clear policy directions. Increasing the accuracy and scope of the analyses may add to our sense of urgency but will not likely shift the direction of needed policy change.

2. Is Ecofootprinting Too Simplistic?
Some commentators have argued that the ecofootprint concept oversimplifies both nature and society and has little predictive value. Both the ecosphere and the economy are dynamic systems, but ecofootprint analysis produces static estimates of a single aggregate variable.

Again, it is true that footprint analysis is not dynamic modeling and cannot directly project the effects of technological change or social adaptation. However, simulation and prediction were never the intent. Ecofootprinting provides a simple ecological camera—each analysis is a snapshot of current demands on nature, a portrait of how things stand right now under prevailing technology and social values.

This in itself is important information. Current “snapshots” indicate that humanity has already significantly exceeded carrying capacity using prevailing technology and that some people contribute significantly more to this ecological overshoot than do others. This is sufficient to suggest approximately how much we must reduce our consumption, improve our technology, redistribute wealth, or change our behavior to achieve sustainability.

Of course, once an initial baseline has been established, subsequent ecofootprint assessments can contribute to a time-series study—repeated snapshots over
years or decades—to monitor progress toward, for example, reducing national ecological deficits or closing the global sustainability gap. (After all, even a motion picture is a series of snapshots.) Such sequential analyses are fully capable of accounting for the actual effects of new technologies, or changes in consumer behavior or cultural values. We can also assess the potential impacts of alternative technologies or settlement patterns on the size of a population’s ecological footprint in static studies. This involves using assumed levels of consumption or assumed technologies (based on real-world data) in the standard calculations to address such questions as, how would a partial shift from fossil fuels to biomass fuels or solar energy affect a population’s ecofootprint?

To summarize this point, ecological footprint analysis is not intended to provide a dynamic window on the future but rather a snapshot in time. As such it can both help to assess current reality and to test alternative “what-if” scenarios on the road to sustainability.

On a related matter, some critics have stressed the impossibility of mapping the state of complex multidimensional processes or systems with a single indicator and that ecofootprint analysis ignores the implications of complexity theory. This comment, while true, misses two points. First, ecofootprinting is not intended to provide a complete picture of any complex system. It generates only one indicator of the state of humanity’s engagement with the rest of nature. To the extent that this index is reliable and has policy relevance to sustainability, it should be used in conjunction with economic, social, or any other indicators that bear on the issues at hand.

Second, although science has certainly gained important insights from complex systems theory—the behavior of dynamical, self-organizing, adaptive systems often confounds standard forecasts and details simplistic approaches to ecosystems management—the fact remains that many phenomena do have simple explanations. In these circumstances, Occam’s razor still applies: there is no need to derive a complex explanation where a simple one suffices.

For example, one can hardly imagine a better example of a complex human-dominated system than the world’s great cities. Cities are a marvel of biophysical, economic, political, social, and cultural subsystems that somehow come together to function as a complex, dynamic, integrated, self-organizing whole. Nevertheless, if any city as currently conceived were enclosed in an impermeable glass dome whose base coincided with its political or geographic boundaries, it would rapidly disintegrate.

The explanation is simple—the city would be starved of resources and suffocated on its own wastes at the same time. This is because most of the ecosystems and biophysical processes supporting the city lie outside our hypothetical bell jar. Ecofootprint analysis measures the city’s (region’s, country’s, etc.) dependence on nature’s services and estimates the ecosystem area needed to produce them. There is certainly room to debate the methods used to make these estimates. However, we don’t need to know anything about city governance or the complex relationships among its physical and socioeconomic subsystems to predict the collapse of our city-in-a-jar or to perform an ecofootprint analysis and assess its implications.

3. The Carbon Assimilation (Fossil Energy) Footprint Is Not a Real Land Use

For many high-income industrialized countries, the fossil energy component may make up half of the total ecofootprint as presently calculated. Because science cannot account for the global carbon budget and there is dispute over the relative roles of terrestrial and marine ecosystems in carbon sequestration, some critics see energy footprint calculations as unreliable or hypothetical. Others don’t regard carbon assimilation as a real land use.

This last criticism reflects our cultural bias that land use requires physical occupancy or the consumption of some tangible product of the land. We are accustomed to thinking of the provision of other (particularly nonmarket) biophysical services of nature, no matter how essential to sustainability, as effective “uses” of landscape. In terms of thermodynamic law and mass balance, it is this cultural bias that needs adjustment, not ecofootprint theory. All energy and material use is “throughput,” implying the generation of wastes, and to the extent that the assimilation and recycling of those wastes (including carbon dioxide) requires an exclusive dedication of land or water, it is legitimate component of ecofootprint calculations.

Returning to the first criticism of energy footprinting, while the details of the carbon budget may be in dispute, there is no question that carbon dioxide levels are increasing in the atmosphere and that these increases represent about half of current carbon emissions from fossil fuel and biomass combustion. This implies that available land and water carbon sinks are insufficient to sequester all anthropogenic carbon dioxide at current rates of emission. In ecofootprint terms, our current global energy footprint is
excessive. We are running a global carbon sink deficit in exactly the same sense that many countries run a food-land deficit.

In short, the notion of carbon sink land is not hypothetical even if the real thing is in short supply. Energy footprint calculations are therefore designed to estimate the area of dedicated carbon-sink forests that would be necessary to assimilate a study population's carbon emissions based on the average estimated carbon sequestration rates of the world's growing forests. In fact, various electric utilities are now planting dedicated carbon sink forests to offset the carbon emissions of their fossil fuel-burning generating plants. Similarly, some countries are contemplating developing carbon sink forests as an alternative to reducing their carbon emissions and to be part of a future system of tradable carbon emission rights. (For example, planting a carbon sink forest would release an equivalent quantity of emission rights for sale on the market.) Note that a dedicated carbon sink forest is an exclusive land use insofar as it cannot be harvested for any purpose such as pulp and paper production that would quickly release sequestered carbon back into the atmosphere.

Finally, we should recognize that any alternative to fossil fuels will also generate an energy ecofootprint. For example, the ethanol equivalent of fossil fuel, generated from biomass, would require a fuel-crop growing area considerably larger than the energy footprint based on carbon sinks. Even solar-based alternatives require that a large land area be appropriated for collector surfaces (though this land need not be biologically productive). The point is that all energy sources and related sinks have a corresponding land equivalent and the present method of calculating an energy footprint may actually be fairly conservative.

VII. EPILOGUE

Whatever its weaknesses, the ecological footprint concept is strong enough to have captured both the scientific and popular imaginations. It is now being applied as an assessment tool by nongovernmental organizations and government agencies in towns, cities, and countries around the world. A small industry of consulting firms has sprung up to develop and commercialize various products based on the ecofootprint concept.

Ecofootprinting seems to concretize the human ecological crisis in a way other energy and material flows studies do not. Knowing our ecological footprint not only makes us conscious of our personal contribution to global change, but also makes us responsible for doing something about it. Pluralistic democracies can work only if the public are well informed about key policy issues and have a keen sense of their capacity to make a difference in improving the human prospect and those of other species. To the extent that ecological footprint analysis helps to generate a more ecologically literate and politically active populace, it will have achieved its most important objective.

GLOSSARY

allozyme Enzyme locus that produces more than one electrophoretic variant.
deme Smallest population unit in population genetic models.
frequency dependence Phenomenon that the dynamics of a given ecological or genetic type depend on its frequency in a population.
gene marker Genetically variable locus that produces distinct variants when analyzed by standard methods such as electrophoresis. It may be based on protein or DNA and may or may not be selectively neutral.
metapopulation Collection of populations that are connected through dispersal and are typically extinction-prone. A key feature is the distinction between local (transient) and regional (persistent) dynamics in one or several interacting species.

phenotypic plasticity Property of a given genotype to express different phenotypes as a function of ecological conditions.
polymorphism Existence of more than one discrete intraspecific type such as distinct phenotypes or genotypes at one locus or several loci.
population structure Subdivision of a given population according to features such as location, age, size, or social status.

ECOLOGICAL GENETICS is an interdisciplinary field of study with the aim to understand adaptation in response to natural selection at the intraspecific level. It applies the principles of neo-Darwinian theory to directly observable microevolutionary processes.

I. INTRODUCTION

Broadly speaking, there are two main objectives at the heart of ecological genetics research: (a) the analysis of the nature and strength of specific selection pressures within a given ecological setting and (b) the genetic basis of the adaptive response. Consequently, ecological genetics draws heavily on two bodies of theory. On the one hand, ecological theory yields predictions about the kinds of adaptations that a given selection pressures might produce. On the other hand, the theory of population genetics provides specific models about allele
frequency changes under different selective regimes and in a variety of population structures.

Hutchinson (1957) succinctly captured the focus of this research program in his famous metaphor of the ecological theater in which the evolutionary play is enacted. In this tradition, E. B. Ford (1964) published the first treatise on ecological genetics. Weary about the possible artifacts of evolutionary experiments that are conducted in the laboratory only, he advocated the study of natural populations as an indispensable complement. To him natural populations provided the ultimately relevant setting in which to investigate natural selection and adaptation. Within the past 30 years, the scope of ecological genetics has become even broader thanks to both theoretical and methodological advances.

The evolutionary analysis of genetically complex phenotypic traits rests on the theory of quantitative genetics. The incorporation of this theory into the conceptual framework of ecological genetics has greatly enlarged the range of phenotypic traits under study. Whereas early studies had mostly focused on the dynamics of visible polymorphisms with a relatively simple genetic basis, adaptations in continuously varying characters such as body size, disease resistance, or courtship coloration have since become amenable to ecological genetic analysis. Moreover, the development of a whole spectrum of genetic markers with varying evolutionary dynamics has provided tools for the study of population structure as well as for the spread of selectively favored genes. More recently, genetic markers have been used for the genetic dissection of complex phenotypic traits.

The ecological setting no longer functions as a mere backdrop to the evolutionary process, as Ford saw it, but provides a research focus in its own right. Ecological theory makes testable predictions about the kinds of strategies that are expected to evolve under a given set of environmental conditions. For example, life history theory defines the optimal schedules of growth, reproduction, and intrinsic mortality. Similarly, behavioral ecology makes predictions about such features as optimal breeding systems or diet breadth. For a broad range of traits, ecological theory establishes the link between a given adapted phenotype and the particular selective agent that prompted its formation.

Ubiquitous environmental heterogeneity produces phenotypic differentiation on a variety of spatial scales across a species range. For any one species, there might be broad differentiation with respect to one trait and at the same time a patchwork of local variants in another. Empirical studies have indeed demonstrated a large amount of ecological variation at the intraspecific level, which covers the range from life history traits over behavior and physiology to morphology. Quite often, these differences are hidden from the casual observer and become apparent only through detailed study that extends over more than one generation of the organism in question. Superficial morphological uniformity over large areas therefore does not imply ecological equivalence. The phenotypic changes may be small, and they need not accumulate to change the appearance of the species in the long term. In fact, they might be partly or entirely reversed when the local conditions change. Yet at any one time they can determine the ecological role that the organisms of a particular population play.

I will use the term 'ecological variants' to emphasize the context-dependence of these phenotypes. Ecological genetics is beginning to tell us not just about the effects of complex ecological settings on the process of evolution, but also about the role of genetic variants in shaping local ecological interactions.

II. GENETIC VARIATION IN ECOLOGICAL TRAITS

A. Genetic Variation within and between Populations

All phenotypic evolution depends on within-population genetic variance. It is this variance that natural selection can mold to produce either distinct locally coexisting variants or differentiation among populations. There is abundant evidence that this substrate of evolution exists for many phenotypic traits. There is genetic variation within populations of the swallowtail butterflies *Papilio <i>zeltocam</i> and *P. <i>oregus</i> for oviposition preference on a number of host plants. Individuals within two populations of the wood frog, *Rana <i>sylvatica</i>, differ genetically in their larval development time. Aphids collected from a single field vary in their resistance to a parasitoid wasp, and among the wasps collected from the same field there is genetic variation in their ability to parasitize the local aphids. The sand cricket, *Gryllus <i>firmus</i>*, shows large within population variation for the duration of the male mating call. Several different genetic types that confer resistance to a fungal pathogen exist within populations of the Australian flax, *Linum <i>marginala</i>*. This list could be extended to include many more examples, all of which underscore the fact that the raw material for evolution exists for a broad range of ecological traits.
The extent to which this variation has been transformed into genetic variation between populations is equally impressive. Garter snakes (*Thamnophis elegans*) in coastal populations of California where slugs are common have a much greater innate preference for eating slugs than those from populations further inland. Female guppies vary in their preference for male color patterns even among populations within the same stream. Sticklebacks (*Gasterosteus*) differ geographically in traits such as courtship behavior and cannibalistic tendency. One population of the milkweed bug, *Oncopeltus fasciatus*, shows strong migratory behavior whereas another more southerly population is nonmigratory. Populations of the spider *Agelenopsis aperia* have diverged genetically in number of traits including territorial behavior, predator avoidance, and diet breadth. The wood frog populations just mentioned differ from each other in larval development time and size at metamorphosis.

### B. Is the Observed Phenotypic Variation Heritable?

In all of the foregoing examples, the genetic basis of the observed variation has been demonstrated through careful experimentation. The easiest way to demonstrate between population genetic differences is to rear field-collected eggs or seeds from different localities under uniform conditions. Differences between the population means in the trait of interest suggest a genetic component. However, the effect could be purely environmental. More resources in one location could lead to better provisioned offspring that reach a larger body size, develop more rapidly, or have greater disease resistance. Such nongenetic effects can be eliminated or at least minimized if one rears two generations in the laboratory and measures the trait of interest only on the second generation.

Controlled breeding schemes are used in order to determine the within-population genetic variation in sexually reproducing species. If the trait in question has a simple genetic basis and gives rise to a small number of distinct phenotypes, it might be possible to infer the number of loci involved from the Mendelian segregations within crosses. However, such a detailed genetic dissection is impossible in the majority of cases in which phenotypic variation is continuous and a function of both polygenic inheritance and environmental influences. In that case, the resemblance between parents and offspring can be used to estimate the so-called heritability of the trait. Heritability is defined as the proportion of phenotypic variance that is due to heritable genetic variation (see Box 1). Care needs to be taken when one extrapolates from laboratory estimates to the situation in the field. Because heritability is a proportion of total phenotypic variance, *Vp*, it can be influenced by changes in any of the components of *Vp*. For example, uniform rearing conditions reduce the environmental

---

### Box 1: Heritability

Quantitative genetic theory is built on a model in which a given phenotype is a combination of genetic factors at a large number of loci, each of small effect, and a random component that reflects the environmental influence. There are several types of genetic effects. An additive component represents the sum of allelic effects. Per locus and allele, the allelic effect can be thought of as the average phenotypic effect that the allele would have if it were placed into a large number of genetic backgrounds within the population. In addition, there may be effects due to dominance. If the joint effect of two alleles in a heterozygote is not equal to the sum of the allelic effects, then the difference between additive and observed effect gives the dominance deviation. Similarly, if the effect of an allele depends on which alleles are present at one or more other locus, one talks of epistasis or of an interaction effect.

The phenotypic variance *Vp* in the population can be broken up into components in an analogous manner:

\[
V_p = V_A + V_D + V_I + V_E,
\]

where *V_A*, *V_D*, *V_I*, and *V_E* are the additive, dominance, interaction, and environmental components, respectively. Because sexually reproducing individuals pass on genes but not genotypes to their offspring, all nonadditive effects that result from particular gene combinations in the parent are not heritable. The resemblance between parents and offspring depends only the additive genetic variance. It is this resemblance that determines the evolutionary dynamics of a trait. Hence, heritability, *h^2*, is defined as the proportion of phenotypic variance that is due to additive genetic variance in the population:

\[
h^2 = V_A/V_p.
\]
variance component and therefore cause an increase in heritability. Nevertheless, laboratory estimates generally give a good indication whether or not the observed variation has a genetic basis.

An alternative method to demonstrate genetic variation within population in a given trait is to perform an artificial selection experiment. If the trait responds to selection, then the base population must have harbored genetic variation at the underlying loci. Experiments of this type are generally successful. Genetic variation for phenotypic traits appears to be ubiquitous, yet not all of it is necessarily available for adaptive change in nature (discussed later in this chapter).

The famous long-term studies of Darwin's finches on the Galapagos Islands have provided not just field-based estimates of heritabilities but also proof of short-term phenotypic change in response to natural selection. For example, the medium ground finch Geospiza fortis on the island Daphne Major shows heritable variation in body weight, wing length, bill size, and tarsus length. These variables are largely correlated, because they are all components of body size. After a period of exceptionally heavy rains, small soft seeds were abundant for the following two years. This food supply differed markedly from the predominantly large and hard seeds of the preceding period of drought. After the rains, the finch size distribution shifted within two years toward smaller birds that showed relatively better survival. Moreover, there was evidence of direct selection in favor of reduced bill width over and above the overall selection on body size.

C. The Alternative: Phenotypic Plasticity

Although genetic differentiation in ecological traits is common, by far not all phenotypic differences between populations need to have a genetic basis, even if they are obviously adaptive. In fact, a surprising amount of intraspecific phenotypic variation lacks a genetic basis. Such variation is referred to as phenotypic plasticity if a given genotype predictably produces different phenotypes under different environmental conditions. This environment-dependent phenotypic repertoire of a genotype is called its norm of reaction. Phenotypic plasticity is thus distinct from random environmental variance due to chance effects that impinge on the expression of traits within a given environment.

In the Texan desert, tadpoles of the spadefoot toad Scaphiopus couchii adjust their development time to variation in pond duration. They are able to accelerate their development in rapidly drying ponds and thus increase their chances to evade death from dessication. However, this apparently adaptive behavior comes at the price of a smaller size at metamorphosis and less well-developed hind limbs, factors which are likely to reduce juvenile survival. Nevertheless, this flexible larval strategy appears adaptive in an environment in which gravid females are seemingly unable to predict pond duration. A large group of examples of phenotypic plasticity involves predator avoidance. The snail Physella virgata delays sexual maturity in the presence as opposed to the absence of a predatory crayfish. Small freshwater cladocerans of the genus Daphnia develop a variety of defensive structures such as helmets, spines, and neck teeth when they receive chemical cues from predators. Some plants produce defensive chemicals once their leaves have been damaged by herbivores. The sun and shade leaves of many plants are another well-known example of phenotypic plasticity.

In heterogeneous environments, phenotypic plasticity is clearly a valuable strategy if it allows organisms to produce the locally optimal phenotype. The evolution of such adaptive plasticity depends on intricate control mechanisms: relevant environmental cues need to be obtained and processed such that the appropriate developmental switches are triggered in time. The ideal norm of reaction matches the local optima in all environments that an organism is likely to encounter. However, this might be difficult to achieve in reality. Environmental cues might provide only imperfect information about future conditions such that the phenotypic expression shows a time lag relative to the optimum. In addition, adaptive phenotypic expression across environments can be constrained by the underlying genetic machinery. For example, a mutation that increases egg size by a constant amount in two environments might move the population mean closer to the optimum in one environment but could cause a shift away from the optimum in the other. What would be preferable instead is a mutation that has an environment-specific beneficial effect on egg size. Moreover, the norm of reaction is more likely to be optimized for those environmental conditions that are frequently encountered rather than those that occur only rarely. The norm of reaction as a whole can be viewed as a trait in its own right. It has a genetic basis and is subject to the selection pressures that particular patterns of environmental heterogeneity produce. As such it is of concern to the ecological geneticist.

D. Are the Ecological Variants Adaptive?

The question of whether the observed phenotypic variation is adaptive arises similarly for genetic variants and
phenotypic plasticity. There are a number of different methods to demonstrate adaptation. For example, one can try to observe the fitness consequences of phenotypic variants directly. In the butterfly Colias meadii, male competition for female is determined partly by flight performance. Males that are capable of prolonged flight and effective courtship display have higher mating success than those that fly less well. A significant proportion of the variation in flight ability and mating success is explained by the males' genotype at two particular enzyme loci. Both phosphoglucone isomerase (PGI) and phosphoglucomutase (PGM) play key roles in the glucose metabolism and thus in the energy supply of the flight muscles. At each of these loci, heterozygous males had better mating success than homozygous males. It appears that heterozygote have a superior balance of enzyme kinetics and stability.

Adaptive differentiation in Trinidadian pupfish, Poecilia reticulata, has been subjected to a particularly detailed analysis. There is marked small-scale differentiation among populations in the intensity of the males' color, despite the fact that all females tend to prefer more brightly colored males. The observed differences were shown to represent a balance between sexual selection and varying predation pressures in different habitats. Differences between populations in schooling behavior matched a priori expectations based on predation levels. The action of natural selection could be directly observed in pupfish that were transplanted from a high to a low predation site in Trinidad in 1976. Within a few years, the males had become brighter in coloration. In addition there was genetic divergence in life history traits that continued to intensify over 11 years. A second experiment in a different river in Trinidad prompted similarly dramatic phenotypic evolution.

III. ECOLOGICAL VARIANTS IN SPATIALLY STRUCTURED POPULATIONS

A. Scale

Given abundant genetic variation within populations and large-scale environmental heterogeneity, one might expect widely separated populations within a species range to evolve different ecological characteristics. It is much less obvious how closely organisms can track small-scale environmental heterogeneity. Intuitively, one might expect that there is a minimal scale of spatial variation below which local adaptation is impossible. This idea is closely allied to the concept of environmental grain. If environmental conditions change on a smaller scale than that on which individual organisms operate, then the environment is fine grained and perceived in an averaged form. On the other hand, the environment is coarse grained if organisms are exposed to only one of several environmental conditions within their lifetimes. The relative scales of spatial variation in selection pressures and of individual dispersal should thus be critical to the question of local adaptation in heterogeneous environments. Furthermore, the rate of new favorable mutants is influenced by stochastic forces, which can slow the rate of adaptation. The strength of this effect depends in turn on the population structure of the organisms.

B. Selection versus Gene Flow

Consider first the case in which a large, randomly mating population exchanges migrants with the remainder of the species gene pool such that a proportion $m$ of the population is replaced with immigrants every generation. In this population, an allele $a$ at a given locus has arisen with a selective advantage $s$ over the wild-type allele $A$. This so-called selection coefficient $s$ applies to individuals with the heterozygous genotype $Aa$ relative to the wild-type homozygote $AA$. The other homozygote $aa$ will initially be too rare to affect the dynamics. For every offspring produced by an $AA$ individual, a heterozygote will on average produce $1 + s$ offspring. Under these conditions, $a$ can become established in the population as long as $s > m$; it will be lost due to the influx of $AA$ immigrants otherwise. In the latter case, migration outweighs selection.

This model is simple, because the only structuring element is the boundary of the population which coincides with the area in which the allele $a$ is favored. A much fuller analysis of spatial dynamics is possible if one assumes a uniform distribution of organisms in space. No populations are delineated. Instead the subset of organisms with which any one individual is likely to interact is determined by the mean dispersal distance, denoted as $\sigma$. More specifically, $\sigma$ represents the standard deviation of the distribution of distances between the organisms' places of birth and reproduction. The dispersal direction is assumed to be random. Thus individuals interact on a local scale that is determined by their movement range, but given enough time genes can in principle flow through the entire gene pool without encountering any physical barriers.

Assume further that the allele $a$ has a selective advantage $s$ inside an "environmental pocket" of specified size and a disadvantage $-s$ outside this region. The
minimum size of an environmental pocket in which a could become established is determined by the critical scale \( l_c = \frac{\sigma}{\sqrt{s}} \). As intuition suggests, this scale increases with the dispersal range of the organisms and decreases with the strength of selection. In two dimensions, the minimum size of the environmental pocket has to be greater than 1.66 \( l_c \). Consider for example a snail species with a mean dispersal distance of \( \sigma = 30 \) m. If a locally favored allele has a fitness advantage of 1%, then the minimum diameter of the pocket is roughly 500 m. In order to halve that diameter, selection would have to be five times stronger. It follows that the environmental grain associated with local adaptation is often much larger than the movement range of the organisms, even in the case of fairly strong selection.

Moreover, the establishment of the locally favored allele does not imply that it will reach fixation throughout the pocket. It might do so only in a small central portion of the range. At the edges, a cline in allele frequency should form whose steepness again depends on \( l_c \); weak selection or a wide dispersal range would create a shallow cline, which allows the alternate allele to occur at appreciable frequencies inside the pocket. The flux of alleles across its edge further implies that the mean fitness of organisms on either side of it will be reduced relative to areas where the locally favored allele is fixed. The distribution of genotypes thus cannot match the local optimum perfectly, unless the selection pressure is very strong indeed. This conclusion depends on the assumption of a sharp ecotone, where the selection coefficients reverse their sign. The effect on mean fitness would be less pronounced if there was a more gradual environmental change.

The same modeling framework can be used to study the dynamics of quantitative traits in heterogeneous environments. Instead of the change in allele frequency, one considers the change in mean phenotype across an ecotone. Phenotypic variance around that mean is created at any one location by a moderate to large number of segregating loci and by environmental effects on the trait. Natural selection tends to shift the phenotypic mean toward the local optimum. The strength of selection is expressed as the rate of decline in fitness on either side of that optimum. The response of a quantitative trait to spatially varying selection is again governed by the balance between this strength of selection and \( \sigma \). In addition, the effectiveness of selection depends on the heritability of the trait: a low heritability limits the influence that natural selection can have on the spatial distribution of phenotypes.

The swamping of local adaptation has been documented in a number of empirical studies. Blue tits (Parus caeruleus) tend to lay their eggs shortly after the bud burst of trees such that the peak abundance of caterpillars on fresh foliage coincides with the greatest food demand of the nestlings. Around the Mediterranean coast of France, bud burst occurs later in evergreen forest than in deciduous forest. Blue tit populations in deciduous forest on the mainland, where this forest type predominates, lay their eggs at the “correct” time. On Corsica, where mostly evergreen forest occurs, egg laying happens later, again in accordance with the local food supply. However, mainland populations in small patches of evergreen forest lay their eggs too early, which entails reduced fecundity. Genetic data indicate that this apparent maladaptation is due to gene flow from predominant deciduous forest.

Similarly, a small riparian population of the spider Agelenopsis aperta has diverged from a second population in dry grassland. In contrast to the grassland site, the riparian population experiences less thermal stress, has a better supply of food, but is subject to stronger predation pressure. There are a number of genetic differences between the two populations. The riparian spiders defend smaller territories and are less likely to escalate when an intruder appears. Their generally more fearful behavior also results in a lower prey capture rate. Despite the qualitative agreement with the local selection regime, the spiders still deviate significantly from the optimal strategy as predicted by detailed theoretical models. They still defend excessively large territories, and they show too much aggressive behavior and too little selectivity in their diet. However, a second and much more isolated riparian population does match the model predictions. Direct and indirect measures of gene flow show that the first riparian site cannot reach the local optimum due to massive influx of genes from the surrounding grassland.

On the other hand, evidence for very local adaptation due to strong selection comes from the classic studies of metal contaminated mine sites. Metal tolerant plant genotypes on the mine are separated from nonmetal tolerant genotypes on normal soil by only a few meters. Similarly, in the marine snail Littorina saxatilis, a cline in allele frequency exists at the aspartate aminotransferase (AAT) locus over only 7 to 10 m at the transition from the submerged surf zone to the splash zone of a rocky shore. After a toxic algal bloom in one year killed all snails in the surf zone, recolonization from the splash zone initially obliterated the allele frequency clime. But within two years, the original allelic distribution was reestablished. The selection coefficient necessary to produce the observed differentiation over such a small spatial scale was estimated to be 0.4.
C. Selection versus Genetic Drift

Chance effects are an integral part of the passage of genes from one generation to the next. Some individuals will always leave more offspring than others even if all have identical fitnesses. If by chance all bearers of a given allele leave more than the average number of offspring, the frequency of that allele in the population increases even though it may not confer a selective advantage. This process of random change in allele frequency is called genetic drift. It interferes with the establishment of favorable mutants and may limit adaptation by reducing the amount of genetic variance in phenotypic traits.

The standard model of drift in a finite population is due to Fisher and Wright (see Box 2). The key feature is the random variance in reproductive success, which poses the risk of imminent chance loss to any rare allele. Even a favorable mutant may disappear from one generation to the next, if it exists in only a few copies and if all its bearers happen to leave no offspring. The probability that an advantageous mutant becomes established in a Wright-Fisher population is \( 2s \), where \( s \) is the selection coefficient of the heterozygote. Thus most mutants that confer a fitness advantage of, say, a few percent will be lost from the population due to chance before they reach appreciable frequencies. In large populations, the deterministic effect of selection begins to dominate once an allele has reached a threshold copy number of roughly \( 1/s \). In small populations, drift influences the fate of common selected alleles. In fact, an allele will be effectively neutral irrespective of its frequency as long as \( s < 1/2N \), where \( N \) is the population size.

Although many local populations may be small, few of these will be completely isolated. It is therefore more realistic to consider the fate of a favorable mutant in a collection of local populations or demes that are connected through gene flow. Imagine a large number of Wright-Fisher populations that exchange individuals at a rate \( m \) through a migrant pool. Allele frequencies in each group of immigrants represent the average for the total population. Gene flow is thus an entirely deterministic force in this model. Moreover, there is no spatial structure, because all demes are equally connected. Taken together, these assumptions make up the so-called island model of population genetics. Remarkably, population subdivision here has no effect on the fixation probability of a favorable allele: fixation is equally likely in a set of \( n \) demes of size \( k \) as in an unstructured population of size \( nk \). The reason for this is that the probability of chance loss of a rare mutant depends on its copy number and not on the size of the population in which it arose.

Although population subdivision per se does not affect fixation probabilities, the addition of local population dynamics does. There is copious empirical evidence in many organisms for pronounced fluctuations in local abundance including the occurrence of local extinctions and (re-)colonizations. The idea that species can persist regionally despite locally transient populations is central to metapopulation theory. As long as changes in abundance are spatially uncorrelated and migration is sufficiently common to ensure the colonization of empty habitat, these local numerical fluctuations tend to average out on the larger scale of the metapopulation. In the population genetic context, fluctuations in population sizes increase the random variance in per capita reproductive success. The more demes within a metapopulation vary in allele frequency, the more likely it is that alleles are differentially affected by local changes in abundance. Drift is thus a stronger force than in the island model with constant local population sizes. Consequently, newly arisen beneficial mutations are more likely to be lost again while they are still rare. However, once they have spread to a few demes, their subsequent fate should be determined by selection.

At present, it is difficult to assess the importance of

---

**Box 2**

**Wright-Fisher Model**

Assume an isolated sexual, diploid population of constant size \( N \) with nonoverlapping generations. To create the next generation, all individuals contribute evenly to an effectively infinite gamete pool. From this pool \( 2N \) gametes are drawn that unite at random and represent the adults of the next generation. For a locus with two alleles, this sampling process implies that the allele frequency in generation \( t+1 \) follows a binomial distribution centered on the frequency in generation \( t \). Thus, there will be successive random changes in frequency through time. Eventually, this process will lead to the fixation of one or the other allele in the population. The probability that a given allele will go to fixation increases with its initial frequency. The average "stepsizes" of the random changes per generation increases with decreasing population size. Thus, the time to fixation decreases with population size.
random drift for the establishment of new ecological variants, because we do not know how much adaptation is limited by the supply of novel mutants. Artificial selection experiments suggest that there is typically sufficient standing genetic variance in natural populations to allow for a response to selection. If intraspecific phenotypic evolution depends mostly on shifts in the frequency of existing alleles, then the main role of random drift might be to slow the process of adaptation rather than to inhibit it altogether. This may be of little consequence, if there is only spatial variation. However, environmental heterogeneity typically has a temporal as well as a spatial component. If the local optimum changes through time, then a delay in the adaptive response due to drift might keep the population away from the optimum for most of the time.

IV. INFERENCES FROM THE SPATIAL DISTRIBUTION OF NEUTRAL MARKERS

A. Direct and Indirect Measures of Gene Flow

Gene flow clearly plays a central role in the dynamics of ecological variants in heterogeneous environments. Its role has been the matter of considerable controversy in the past. Does wide ranging gene flow impose limits on intraspecific differentiation or is gene flow on the contrary so limited that populations of a species behave as nearly independent evolutionary units? Based on the available evidence, the latter view is closer to the truth. Nevertheless, it is difficult to predict the potential for local adaptation and differentiation for any given species. Reliable estimates of gene flow are thus highly desirable. They might be obtained by monitoring the movement of marked individuals. However, such direct estimates typically give an underestimate of gene flow. Long distance dispersers will often be missed, yet they play an important role in the spread of genes. Mark-recapture studies provide a snapshot of dispersal whereas a longer-term average is required for evolutionary inferences. On the other hand, not all observed movement necessarily leads to gene flow. For example, immigrants might be less successful than residents in the competition for territories. Much effort has therefore been devoted to the developments of indirect measures of gene flow that can provide a suitably averaged estimate. Most of these methods are based on the spatial distribution of neutral genetic markers.

Consider again the island model: a large number of demes, each of constant size $N$, are connected by gene flow at a rate $m$ via a common pool of migrants. The overall frequency of a certain selectively neutral allele in the population as a whole, and consequently in the migrant pool, is $\hat{p}$. Genetic drift within demes produces variance in $p$ across demes as a function of local population size. Without gene flow, this process would inevitably lead to the random fixation of one or the other allele in each deme. With gene flow there is an equilibrium amount of differentiation: the divergence among demes due to drift is balanced by the homogenizing effect of gene flow such that the variance in $p$, $V_p$, is constant. For a locus with two alleles, Sewall Wright defined the standardized variance in allele frequency as $F_{st} = V_p / \hat{p} (1 - \hat{p})$ and showed for the island model that

$$F_{st} \approx \frac{1}{1 + 4Nnm}.$$ 

The degree of differentiation among demes in the island model thus depends on the number of migrants per deme per generation. Consider a given combination of $N$ and $m$. An increase in $N$ reduces random drift such that a smaller migration rate suffices to keep $V_p$ constant. The two forces exactly balance each other. The analysis of the island model shows that only a small amount of gene flow is enough to maintain neutral genetic variability within demes. The threshold number of migrants below which there is a tendency for demes to fix by chance one or the other allele is $Nnm = 0.5$, which is equivalent to one migrant every other generation or an $F_{st}$-value of 0.33.

B. Interpreting $F_{st}$

At equilibrium, $F_{st}$ expresses the balance between gene flow and drift. As such it can be estimated from the distribution of neutral alleles in any set of populations. However, in principle no inference can be drawn about the relative importance of the two component processes. A given $F_{st}$ estimate may stem from a set of large populations that are connected by weak gene flow or from small populations that exchange migrants at a correspondingly higher rate. Even the interpretation of $Nnm$ as the number of migrants is problematic, because real populations differ in important respects from the island model.

Consider populations that fluctuate in size around a certain mean abundance $\bar{N}$. Random drift is disproportionately affected by the smallest population sizes. Therefore, allele frequencies are subject to stronger stochastic forces in this fluctuating population than in a population of constant size $\bar{N}$. In many species, the variance in reproductive success is much larger in males than in females: few males may sire most of the offspring.
while others do not contribute to the next generation at all. The pool of paternally transmitted alleles is therefore much smaller than the census number of males would suggest. Again, drift forces are stronger as a result and correspond to those in a much smaller ideal population (cf. Box 2). The effective population size \( N_e \) of a natural population is equal to the size of an ideal population that experiences the same amount of genetic drift. In the previous two examples and in natural populations in general, \( N_e \) will be much smaller than the census population size. It follows that \( F_{st} \) can only be translated into the rather abstract quantity \( N_e m \). \( F_{st} \) describes a pattern of differentiation. Without additional information about the population structure at hand, it is difficult to infer a process from it.

Further complications arise when \( F_{st} \) estimates are low due to recent common descent of the populations rather than high levels of gene flow. Imagine a species that rapidly colonizes an area of patchy habitat from a large pool such that all local populations start out with nearly identical allele frequencies. If gene flow is subsequently reduced to a low level, differentiation among demes will increase with time until the migration-drift equilibrium is reached. During this time period, estimates of \( F_{st} \) reflect past history as well as current processes. The relevant time scale in generations is given in the island model by \( 1/m \) for \( N_e m < 1 \) and by \( N_e \), otherwise. These results imply that \( F_{st} \) equilibrates faster than any other measure of genetic differentiation.

C. Extrapolation to Selected Variants

Finally, it is difficult to extrapolate from the dynamics of neutral genes to those that govern selected variants. The fate of a novel mutant is in the first instance determined by the balance between selection and drift within a deme, which depends on \( s \) and \( N_e \), whereas its spread to other demes, once it has reached appreciable frequencies, depends on \( m \). Thus, predictions about the fate of such a mutant in structured populations require knowledge of \( s \), \( N_e \), and \( m \) separately. Different population structures that give rise to the same \( F_{st} \) could differ with respect to adaptive processes.

There is a large body of empirical literature on indirect measures of population structure that covers a broad range of taxa. These studies indicate that the balance between gene flow and genetic drift allows in most cases for no more than moderate differentiation in allele frequencies at neutral loci. Most \( F_{st} \) values lie between 0 and 0.1; only very few exceed Wright's threshold of 0.33, which implies that most demes tend to be near fixation at a given locus for some neutral allele. The typically low estimates of \( F_{st} \) indicate that local populations are unlikely to be so small and isolated that adaptive processes are severely compromised. The populations are either large and should therefore generate a reasonable supply of new mutations on their own or they are so well connected that they receive a steady stream of new alleles from elsewhere. Even if genetic markers indicate limited within-population variation, there may still be considerable genetic variance in phenotypic traits. In the latter, genetic variation can usually arise at a large number of loci, whereas the single locus mutation rate strictly determines variation in markers.

Limited differentiation at neutral loci does not imply uniformity in adaptive traits. This is illustrated by a number of studies. For example, Scots pine, *Pinus sylvestris*, has a circumpolar distribution occurring from Western Europe across Siberia to northern North America. Allozyme studies have detected only very slight genetic structure across this vast distribution range (\( F_{st} = 0.02 \)). However, direct assessments of the fitness of transplanted versus locally grown trees indicate important differentiation in frost hardiness, the onset of flowering as well as a number of other ecologically important traits. Similarly, the endemic perennial *Primula scotica* has a fixed genotype at 14 out of 15 allozyme loci. Yet common garden experiments reveal significant heritabilities in 6 out of 11 morphological characters. The number of seed capsules, a fitness-related trait, has a heritability of 0.25. Moreover, roughly one-third of all phenotypic variation is due to differences between populations. Clearly, the remaining 15 populations of this species in the far north of the British Isles have not lost their ability to respond to environmental change.

V. THE GENETIC BASIS OF ECOLOGICAL VARIANTS

A. Simple versus Complex Traits

Every phenotypic trait results from a complex interplay of many gene products that influence its mature expression over the course of ontogeny. A mutation at any one of the underlying loci can in principle alter a trait. Yet only those loci that actually are polymorphic at any one time contribute to the trait's heritable variation. It is the genetic basis of phenotypic variation and not of the phenotype per se that is relevant in the context of evolutionary analysis. Traditionally, traits have been referred to as simple if their heritable variation could be attributed to a small number of loci on the basis of crossing experiments. In contrast, a complex trait is typically based on many polymorphic loci as well as
on random environmental variation. Its evolutionary
dynamics are best analyzed statistically in the frame-
work of quantitative genetics. However, recent develop-
ments suggest that the dichotomy of simple versus com-
plex traits is somewhat misleading. Whether few or
many loci determine phenotypic variation appears to
be more due to the nature of selection than to an
inherent property of the trait. Moreover, modern ge-
netic techniques demonstrate that loci of large effect
are segregating for traits that were thus far believed to
fit the quantitative genetic model, which assumes a
large number of loci, each of which has a small effect
on the phenotype.

B. Are Major Mutations Important
for Adaptation?

Mutations of large effect have until recently been
thought to play only a limited role in phenotypic evolu-
tion. After all, when a large and random change is
applied to an integrated organism, it is much more
likely to cause harm than good. According to this view,
such major deleterious mutations are efficiently re-
moved from the gene pool by natural selection, and
most adaptive evolution occurs through the accumula-
tion of mutations of small effect. Recent theoretical
analyses (Orr, 1998), however, have cast a new light
on the genetic basis of adaptation. The contribution
of large mutations depends on their frequency of occur-
rence, their chance of being advantageous, and finally
on their chance of fixation given that they are advan-
tageous. The first two criteria indeed limit the import-
ance of large mutations: they are presumably rare and are
relatively unlikely to improve fitness. Nevertheless, the
small set of large advantageous mutations will be impor-
tant for evolution if selection is strong and if the current
mean phenotype in the population differs from the optim-
um by a large amount. As adaptation moves the mean
toward the optimum, mutations of decreasing effects
should become fixed. One should thus expect that espe-
cially adaptation to novel conditions involves both mu-
tations or large and of small effect, which tend to be-
come fixed early and late in the process, respectively.

C. The Strength of Selection Shapes
Genetic Architecture

The foregoing discussion suggests that the genetic basis
of ecological variants is intimately linked to the nature
of selection. In fact, the classic case studies of ecological
genetics such as the banding patterns of snail shells
and the color morphs of butterflies have often been
considered to be special cases because of the apparent
simplicity of the traits. Although they may well be end-
points of a spectrum, it appears that this spectrum is
defined not by some measure of trait complexity but
by the strength of selection involved. It is also not
surprising that many of these adaptations such as the
cryptic dark coloration of moths on sooty tree trunks
(industrial melanism) are responses to strong anthropo-
genic selection pressures.

The application of insecticide is an example for the
most extreme selection pressure imaginable: the aim
is to kill 100% of the insect population. All cases of
insecticide resistance that have been analyzed in detail
are based on one or two loci of major effect which
are able to transform a susceptible population into a
resistant one. They need to be either present in the base
population before the application of the pesticide or
arise soon thereafter. There are some indications that
mutations that allow for adaptation to extreme anthrop-
genic selection pressures might be in short supply.
For example, in the blowfly Lucilia cuprina, resistance
to each of two different insecticides produced resis-
tances at the same two loci in replicate selection lines.
Under less stringent artificial selection, polygenic resis-
tances were observed involving different loci in different
lines. These results imply that there were many avenues
to evolve weak resistance, but there was only one ge-
etic way to achieve resistance to a given insecticide
applied at field strength. Nevertheless, the rapid evolu-
tion of resistances in insects and weeds argues against
a strong limitation on available mutations.

Minor loci that contributed to a polygenic response
were similarly observed in plants that had evolved heavy
metal tolerance: there was heritable variation within
distinct resistance classes, each of which corresponds
to a major mutation. Similarly, in the case of industrial
melanism in Biston betularia, a trait that is largely attrib-
utable to a single dominant allele, one finds additional
alleles of relatively smaller effect. These observations
underscore the point that the genetic variation in any
of these traits is based on a spectrum of allelic effects.
Which of these alleles contributes to a given adaptive
response should depend on the selection pressures and
the difference between the population mean and the op-
timum.

In comparison to the application of insecticides, arti-
ficial selection experiments are more benign because
the experimenter needs to keep the selected lines going.
Here too, alleles of large effect contribute a large part
of the selection response, but typically the response is polygenic. The critical question is how often natural selection on ecological variants is so strong that major mutations are fixed. It seems likely that microevolutionary processes that are of interest to the ecological geneticist will often fall into that category simply because only the rapid response to strong selection is easily observable. Moreover, all of the preceding examples involved so-called directional selection in which the population mean is adjusted to match a new phenotypic optimum. If the population mean is at the optimum, then selection is stabilizing and mutations that cause large deviations from the mean are strongly selected against. The relative importance of stabilizing versus directional selection in natural populations depends on whether or not populations are typically in a state of selective equilibrium. This is at present an unanswered question of considerable interest.

D. QTL Mapping

Even those traits that so far have appeared to have a complex genetic basis have recently become amenable to detailed genetic dissection. The critical methodological advance has been the development of a nearly unlimited supply of genetic markers. These can be used to identify relatively small genomic regions that carry one or more loci affecting a given trait. These regions are referred to as quantitative trait loci or QTLs. The approach requires two or more populations that have diverged in some character of interest and ideally have fixed alternate alleles at each marker locus. Through controlled crosses, one initially establishes a so-called linkage map that represents the relative location of the markers to each other. With the help of further crosses, one searches for statistical associations between the expression of a given trait and a marker locus. Such an association is equivalent to finding a QTL for that trait in the vicinity of the marker. Studies of this type have uncovered a surprising number of loci of large effects that segregate in natural populations. Thus major loci may explain a large proportion of phenotypic variation even in traits that show continuous variation and conform phenotypically to the model of quantitative genetics.

E. Ecological Consequences of Genetic Structure

Whereas the genetic basis of a selection response might be in part determined by the selective regime under which it arose, a given genetic structure can subsequently influence ecological processes. A famous example in this context is the analysis of the mimetic colorations of Heliconius butterflies. Both H. melpomene and H. erato exist in a number of distinct color morphs or races that occur in nonoverlapping regions of their respective species range. Both taxa are unpalatable to avian predators. In any one location, birds learn to avoid the local wing pattern that is shared between co-occurring Heliconius species form a so-called mimicry ring. The maintenance of local color morphs is due to frequency dependent selection: the locally frequent wing morph is well protected against predation because birds have learned to avoid it, whereas any rare morph that might appear suffers predation from naive birds that have yet to learn about its distastefulness.

Through the analysis of numerous hybrid crosses between the local races, the total phenotypic variation of the different color morphs within each of the two species could be attributed to 22 and 17 loci respectively. Some of these have large effects on the formation of pattern components such as wing bands and spots, whereas others modify some detail of an existing pattern. There are complex dominance relationships as well as interactions among loci, such that the effect of a given allele at a particular locus depends on the individual genetic background in which the allele is placed (epistasis, cf. Box 1). For any one pair of geographically adjacent mimetic forms within a species, one finds genetic differences at no more than four major loci plus some small number of modifier loci. Nevertheless, this number of loci is sufficient in principle to produce a large number of recombinants upon interbreeding in areas where the racial distribution ranges adjoin. These animals with recombined wing patterns should suffer greatly increased predation, as any of the local birds would not recognize them as distasteful.

In contrast, there is another mimetic system that involves the swallowtail butterfly Papilio memnon. This butterfly is edible, but females gain protection from predation because they mimic other distasteful species. In this case, one finds several different female morphs within populations, which are due to allelic variation at a so-called supergene consisting of several tightly linked loci. As a consequence, only a limited number of phenotypes is produced, each of which may be mimicking different models. The high fitness of these morphs is in part a consequence of the underlying genetic structure. The existence of several unlinked loci as in the case of Heliconius would preclude intrapopulational variation in color morphs, because too many of the possible recombinants would not be adaptive.
VI. LIMITATIONS TO THE EVOLUTION OF NEW ECOLOGICAL VARIANTS: TRADEOFFS

A. Antagonistic Pleiotropy

Although the broad spectrum of genetically determined ecological variation within species underscores the efficacy of natural selection, organisms are not infinitely malleable. Even if a trait displays heritable genetic variation, it may not be able to evolve toward a new phenotypic optimum, because the necessary genetic changes could be deleterious with respect to some other trait. If a given set of polymorphic loci affects more than one phenotypic trait, these loci are said to have pleiotropic effects and the traits in question are genetically correlated. If an adaptive change in one trait causes a fitness reduction in a correlated trait, one speaks of antagonistic pleiotropy. In that case, the realized set of phenotypes in a given natural population can at best represent the optimal tradeoff between the conflicting selection pressures on correlated traits.

Direct evidence for such antagonistic pleiotropy comes from a number of laboratory experiments in which a given trait is altered by artificial directional selection for a number of generations. When the selection regime is then relaxed, one observes in the following generations a return of the trait mean toward the original value. This reversal reflects natural selection in the opposite direction due to some correlated trait.

B. Life History Tradeoffs

Strict negative genetic correlations for fitness are at the heart of life history theory. The schedules of growth, reproduction, and mortality together determine the life history of a species. Although one can imagine an arbitrarily fit organism that maximizes its fitness through independent optimization of each life history component, actual life histories are constrained through a web of genetic correlations. The most obvious examples are those that have to do with the allocation of energy. For any one bout of reproduction, for example, a given amount of energy can be allocated to few large or many small offspring. Within-population genetic variation in offspring size and number implies polymorphism at one or more allocation loci. More often, life history tradeoffs involve time delays. For example, deer hinds (Cervus elaphus) with fawn enter the winter season with smaller fat deposits and suffer a higher mortality than those that did not have a fawn that summer. Similarly, female collared flycatchers (Ficedula albicollis) that first reproduce at the age of 1 have lower subsequent reproductive success than those that delay first reproduction until they are 2 years old. Aside from tradeoffs between current and future reproduction, those between early reproduction and life span and between reproduction and growth have been demonstrated. In most cases, their physiological and genetic basis remains to be discovered.

Genetic variation in life history strategies allows for their adaptive adjustment. For example, an environment in which adults suffer high mortality from predation selects for earlier reproduction. This strategy brings a net gain in fitness, even if there is a correlated increase in intrinsic adult mortality. The latter is of no consequence in this environment. Due to their intimate relationship with fitness and strong dependence on ecological conditions, one expects and does in fact find abundant intraspecific variation in life history strategies. Moreover, by its very nature local life history adaptation creates genotypes that trade off their fitness in one habitat against that in another one and thus creates ecological specialization.

C. Threshold Traits

A remarkable illustration of a tradeoff is the wing dimorphism in a variety of different insect species. Even within populations, one finds individuals with large functional wings as well as those that are flightless. This is an example of a so-called threshold trait, in which a polygenic basis produces two distinct phenotypes through a developmental switch. Winged individuals are clearly better able to disperse when local conditions deteriorate, yet the production of flight muscles diverts energy away from other organismal functions. The relative proportion of the two types tends to correlate with the local ecological conditions. In the cricket Gryllus firmus, the production of a functional flight apparatus entails reduced fecundity in females and the production of a less attractive, shorter mating call in males. The tradeoff, however, goes beyond this simple dichotomy in energy allocation between the two morphs and involves an intricate genetic correlation: in families with a high proportion of long-winged offspring, even flightless sons produce a relatively shorter call than is seen in flightless male offspring from mostly short-winged families.
D. Are Genetic Correlations Constant?

Genetic correlations need not be unbreakable. Like heritabilities, they reflect the genetic architecture in a given population at a given time. For example, only in one of two populations of Rana sylvatica was there a strong and positive genetic correlation between development time and size at metamorphosis, while the other two traits were uncorrelated in a second location. With time, new mutations can change an existing genetic link between two traits. In the sheep blowfly, Lucilia cuprina, the newly evolved resistance to an insecticide initially entailed a fitness cost in the absence of the toxin. This cost was subsequently eliminated through the appearance of additional mutations. These so-called modifiers restored the fitness of the resistant genotype to the same level as that of susceptible wild type. Nevertheless, genetic correlations undoubtedly constrain phenotypic evolution especially over the relatively short time scales that are of interest to the ecological geneticist. They are a likely explanation for the fact that plant genotypes that confer resistance to herbivores typically do not reach fixation in natural populations. Even though genetic correlation may often not be strong enough to rule out an adaptive response, they can certainly slow the process so that a given population might not be able to track spatio-temporal environmental heterogeneity efficiently.

VII. ECOLOGICAL GENETICS OF SPECIES INTERACTIONS

The joint analysis of population genetics and population dynamics has long been on the agenda of ecological geneticists. In fact, the integration of these two large bodies of theory seems like a natural focus in a field of research that is by definition positioned at the interface between ecology and genetics. Yet progress has been hampered by the conceptual and practical complexity that any natural study system poses. Most progress has been made in the fields of host-pathogen and host-parasite interactions.

If several host genotypes interact with several pathogen genotypes, then the question arises how such genetic diversity can be maintained. Imagine a system in which a host population harbors a resistance alleles for every virulence allele in the pathogen population, but each host individual carries only one such allele. The host is resistant against the pathogen strain with matching allele, but it will be infected by all other pathogen strains. Frequency dependence in such a system can in principle lead to a stable equilibrium of multiple genotypes, but the approach to equilibrium in a single population is typically marked by pronounced fluctuations in allele frequency such that most variants could be lost in the process. In a single population of constant size, the system only yields abundant polymorphism when there is a large fitness cost to resistance and virulence. However, if one allows for numerical and genetic dynamics and moreover adds spatial structure, coexistence is possible even under much reduced costs. Genetic types that have been lost locally can be reintroduced through gene flow. Even if the disease dies out in a local population because only resistant host genotypes are left, a colonization event elsewhere may help to reset the system. Stochasticity in local encounters breaks the violent oscillations of frequency-dependent dynamics.

Metapopulation dynamics of this sort have been extensively documented in the interaction of the plant Silene alba and its pathogen Ustilago violacea. Heritable resistance levels within a host population ranged from 0 to 100%. However, little is known in this system about pathogen virulence types. A lack of close matching in the occurrence of host and pathogen strains was observed in the Australian flax Linum marginale and its fungal pathogen Melampsora lini. The local co-occurrence of genotypes of host and pathogen in a set of interconnected populations gave little indication that the latter tracked the frequencies of their hosts. Instead, the pattern appears rather haphazard. Gene flow together with local extinctions and colonizations are likely causes of this pattern.

One of the ecological consequences of diverse host and pathogen genotypes is that the chance of epidemics is small and leads to no more than local outbreaks. The metapopulation dynamics are also likely to affect the evolution of resistance and virulence. Consequently, the joint numerical and genetic dynamics are relevant to the process of coevolution. The so-called geographic mosaic theory of coevolution postulates that the evolutionary interactions among closely interacting species vary qualitatively from one population to another depending on the transient local mix of genotypes. In a few places at any one time, these local interactions may be strong and persistent enough to produce truly coevolutionary dynamics. This idea integrates within-population genetic and numerical dynamics with metapopulation dynamics and spatially varying selection. Complex dynamics of this type clearly are commonplace in nature. The development of this theory prom-
ises new insights into microevolutionary processes of species interactions.

ECOLOGY IS THE STUDY OF THE DISTRIBUTION AND ABUNDANCE OF ORGANISMS. Ecologists attempt to understand the factors that both promote and limit biodiversity. In practice, the science of ecology blends observation of natural systems, manipulation of environmental and biotic factors in the field, more highly controlled laboratory or microcosm studies, and both qualitative and mathematical theory. The major concepts and theories of ecology concern the dynamics of populations as well as the patterns and processes of communities and ecosystems.

GLOSSARY

coevolution Process of reciprocal genetic changes in interacting species that result from the mutual selection pressures that strongly interacting species can exert on one another.

keystone species Species whose presence fundamentally alters the structure or function of an ecological community or ecosystem.

metapopulation Collection of subpopulations connected by dispersal. Subpopulations within a metapopulation may undergo local extinction and subsequent recolonization.

threshold theorem of epidemiology If the density of susceptible individuals in a population falls below some critical threshold, then a disease may not be able to maintain itself in the population.

1. HISTORICAL DEVELOPMENT OF ECOLGY’S CENTRAL CONCEPTS AND THEORIES

Ecological theory has three major origins: (1) attempts to manage fisheries, pests, or wildlife, (2) explorations of patterns in nature—especially spatial pattern and the apparent order of species assemblages, and (3) investigations of “the balance of nature” (and how that balance can be disturbed). To some extent, ecological theories developed separately in the sub-disciplines of plant and animal ecology. For example, quantitative plant ecologists tended to focus on patterns of plant dispersion and relationships between individual plants and their environments, whereas animal ecologists focused more on population dynamics. But the most important early
ecological models came from neither plant nor animal ecologists; instead these pioneering models were largely contributed by scientists from other fields, such as physics, mathematics, and human demography.

The acceptance of mathematical approaches into mainstream ecology has been slow (and some might argue that mathematical theory is still not accepted by many ecologists). The reluctance of ecologists to embrace mathematical models reflects the different ways that empiricists and theoreticians view the world. In particular, whereas field ecologists are typically concerned with the uniqueness of their study systems and pay attention to the role of history and “details,” mathematical ecologists often neglect the role of history and gloss over details to arrive at more general results. Fortunately, there has been increasing reconciliation between the theoretical and empirical approaches to ecology, largely because modern ecological theory has matured enough to allow examination of how details such as age structure, spatial heterogeneity, or environmental variation alter the generalities derived from more simple models. In addition, recent ecological theory relies less on “equilibrium analyses,” which tended to downplay historical effects.

Whereas many branches of natural science are grounded in some core body of theory and first principles, this is not the case for ecology. Instead, ecological theory is remarkably varied and discordant, with natural selection as the only fundamental “law.” Moreover, although one could argue that little in ecology makes sense without the perspective of natural selection, there is a great deal of useful ecological theory that never makes any contact with evolutionary principles. Thus, even though all ecologists accept evolutionary theory, different subfields of ecology do not share a common view of the most important theoretical questions (such as ecosystem analysis versus population biology). However, in spite of this notable lack of a single unified and ascendant ecological theory, current attention to conservation and resource management has stimulated the practical integration of models that range from evolving gene pools to ecosystem nutrient cycling.

II. POPULATION DYNAMICS

Births and deaths are the bottom line of ecology—this is because variation in birth and death rates determines the distribution, density, and dynamics of populations. However, most population models avoid tabulating particular sequences of births and deaths and instead keep track of average rates of change. In most cases, models of population change are not precise forecasting tools, but rather are conceptual frameworks with which to understand when a population is expected to stay constant as opposed to fluctuate wildly. Models are also valuable for asking how external factors such as harvesting and habitat destruction might alter a population’s long-term fate. Two fundamental features of population dynamics are inescapable:

1. Because of resource limitation, per capita rates of change for populations decline with increasing density.
2. If there is any time lag in the response of demographic rates to declining per capita resources, the population may overshoot their resources, then crash to low levels, then rebound, only to repeat the process again.

Formal mathematical representations of these principles have led to elegant models of nonlinear population dynamics. “Nonlinear” refers to the fact that the rate of change in populations varies nonlinearly with changes in population density. As a consequence, under a wide variety of circumstances populations are prone to fluctuate, sometimes so erratically that a graph of numbers through time would appear random, and such that any small changes in initial population size become amplified through time (an attribute called chaotic dynamics). This theoretical result is now widely appreciated by ecologists, but its illumination in the 1970s represented a major advance in the field. First, it emphasizes that populations may fluctuate without any environmental or climatic variation. Second, the phenomenon of chaos illustrates how complicated and unpredictable population dynamics can arise in the simplest systems, if nonlinear feedbacks are strong enough to cause the overshooting of equilibria followed by pronounced population crashes. Prior to the development of a theory of chaotic and nonlinear dynamics there was a tendency to always look to the external environment as the cause of population fluctuations, and to think that complicated patterns of fluctuation must have complicated explanations.

Applications of population theory have largely focused on three types of species: rare species that are of conservation concern, species that reach extraordinarily high population densities (“outbreaks”) that cause severe damage to crops or forests, and finally species that are harvested by humans, especially many fish species.

To assess threats to rare species, ecologists have developed a suite of analytical tools collectively known as population viability analysis (or PVA). PVAs are com-
monly used to estimate the probability of extinction under a range of alternative management strategies or to quantify the minimum number of individuals that will ensure survival of the species. PVA models may incorporate the effects of environmental and demographic stochasticity, catastrophes, and spatial structure and movement (see Section V). One approach that has been quite successful entails detailed demographic analyses that keep track of the birth and death rates for groups of similar individuals. When the groups are defined by age of the organisms, a life table can be developed. However, demographic matrices are flexible enough to incorporate groups based on size, stage, or sex, as well as age. The principal advantage of demographic matrices is that one can ask how sensitive the growth rate for the entire population is to changes in the survival or fecundity of a particular class of individuals. This approach is being used increasingly to compare the efficacy of alternative management scenarios. Analyses of this nature have revealed that adult survival is generally a very sensitive demographic parameter for long-lived species, whereas fecundity is often the most sensitive parameter for shorter-lived species. These findings have shaped a number of conservation decisions—for example, a demographic matrix applied to loggerhead sea turtles made it clear that even substantial improvements in the survival of baby hatching turtles would provide little benefit to the turtle population, whereas elevating the survival of adults could dramatically help this threatened long-lived species.

For outbreaking or pest species, population ecologists have asked what factors lead to population outbreaks and whether certain life-history traits are shared among those species with a propensity to outbreak. The goal of this research is to determine how best to control these species and prevent future outbreaks from occurring. One quantitative focus concerning outbreaking species has been on the role of time lags. Time lags can occur when, for example, a population does not respond immediately to changes in its own density, perhaps because the individuals store up energy reserves. Alternatively, a population may lag in its response to one of its natural enemies, such as a predator or a disease. Any such time lag, especially when combined with a high potential for population growth, can lead to dramatic oscillations in population abundance.

Finally, for harvested species there has been a focus on determining the maximum sustainable yield (MSY) that can be harvested from a population without placing it at risk of extinction. Clearly most natural populations do not grow without bound, but rather are regulated around some equilibrium density, called the carrying capacity of the environment. This assumption of density-dependent population growth (a reduction in the per capita rate of population growth as population density increases) is central to the calculation of MSY. In particular, theory predicts that the largest number of individuals can be sustainably harvested when a population is maintained at approximately half its carrying capacity. Although density dependence is a central tenet of population ecology and particularly of fisheries management, actually detecting density dependence from a time series of population abundance estimates remains difficult, and discussions about the appropriate methodology have been contentious. A large part of the difficulty in detecting pattern is the random variation inherent in estimates of population size. While part of the variation is due to observer error, a large fraction is often due to random fluctuations in the environment that change either the population growth rate or the equilibrium population size from one year to the next. It is straightforward to investigate in theory the interplay of density dependence and these external sources of variation. The bigger challenge lies in developing management models for real-world data sets in which the apportionment of variation among observer error and different effects of environmental variation is unknown. Fisheries biologists have made the greatest progress in this area, but the theory is still incomplete; it remains especially challenging to connect models of population dynamics to economic models that integrate the biological and economic aspects of resource management.

III. THEORIES OF SPECIES INTERACTIONS

The traditional core of mathematical ecological theory involves dynamical models of pairwise interactions between a predator and its prey, or between two competing species. Both of these types of interaction lead easily to the extinction of species—either because a predator imprudently consumes its entire food base or because a superior competitor usurps so much of the resources that other species cannot make a living. Not surprisingly then, the focus of species-interaction theory has been to ask what processes mitigate the tendency toward extinction in these antagonistic interactions.

Although the elimination of an inferior competitor seems inherent to competitive interactions, in nature we regularly find many species coexisting. Early on, theoretical ecologists suggested that coexistence gener-
ally occurs only when the populations of the two species are limited by different resources. In other words, coexisting species must occupy distinct ecological niches. The concept of the ecological niche motivated numerous attempts to quantify just how different two species must be in order to coexist. Measures of various traits related to resource use, such as beak size, body size, and habitat preferences, were often invoked as evidence for “niche partitioning” (the use of different resources by potentially competing species). Careful attention to such data indicated that this evidence was often not as clear-cut as initially assumed, and research was devoted to alternative explanations for the coexistence of competitors. A second generation of competition models made it clear that competing species may readily coexist without any niche partitioning, as long as some form of disturbance interrupts the exclusion of the inferior competitor. Such disturbance can take the form of predation, or abiotic factors such as storms or droughts. Implicit in disturbance-mediated coexistence is the concept of a trade-off between the ability to be a superior competitor and the ability to recover from a disturbance.

As with competition models, early models of predators and their prey suggested that stable coexistence would require certain special conditions. In the absence of these conditions, predators tend to drive their prey to extinction, and then, having exhausted their food supply, go extinct themselves. One answer to the dilemma of predator–prey coexistence was provided by a classic series of laboratory experiments using predatory mites and their mite prey that live on oranges. These experiments demonstrated that, in a simple "landscape" (a tray of oranges), the mite predator was able to quickly find and consume all of its prey, leading to the extinction of both species. However, more complicated laboratory microcosms that impeded the predator’s movement could prolong the coexistence of the predatory and prey mites by as much as an order of magnitude—slower predator movement allowed the prey to stay "one orange ahead" of predators and enjoy a temporary refuge from attack. Subsequent mathematical models have made it clear that this is a general principle: predator–prey interactions can be stabilized by any attribute that affords prey some refuge from attack. The refuge can take the form of patches of habitat, or age or size classes of individuals that enjoy low attack rates. With spatial refugia, there is still a tendency for predator–prey systems to fluctuate locally, but different patches will fluctuate out of phase so that the entire collection of patches never goes through a phase in which prey are everywhere absent.

In the last three decades predator–prey theory has been modified to model plant–herbivore and host–disease (or parasite) interactions. These models are similar to classic predator–prey theory in structure and in terms of the possible dynamics associated with the interactions. However, there are also important differences. First, the effects of herbivory are not as obvious as those of predation—individual plants are usually not killed outright by herbivory, and some plant species may actually perform better after being partially consumed. Also, studies of herbivory have typically had more of an evolutionary emphasis in focusing on how herbivores act as selective pressures on plant traits, especially plant structural and chemical defenses.

Host–disease interactions also have been a rich subject for mathematical modeling, with much of the initial theory originating from work on the epidemiology of human diseases. Epidemiological models reveal that disease spread depends on the transmission rate, virulence, latency, and infectious period of the disease, as well as the density of susceptible hosts. More specifically, a disease will be unable to persist if the density of susceptible hosts falls below a threshold value. Immunization programs represent an application of this result, sometimes called the “threshold theorem of epidemiology.” Immunization can lead to the elimination of a disease, because if a sufficiently large percentage of the population is vaccinated, an infected individual will, on average, fail to transmit the disease to a susceptible host before the infected host either recovers or dies. Epidemiological models further reveal that diseases can potentially maintain host populations at low levels or cause pronounced cycles in the host population.

Although much theoretical work has focused on interactions within species pairs, species do not, of course, occur only in pairs in nature. Most natural communities include scores or hundreds of different species, simultaneously interacting with one another to various degrees. Recently, increased attention has been paid to relatively complex interactions occurring among multiple species. The food web or, more generally, interaction web has proven to be a useful way to visualize the interactions among large groups of species with vertical links representing trophic interactions and cross-links representing competitive or mutualistic interactions (Fig. 1). Enormous effort has been focused on understanding the relationship between the patterns of connections among species and the traits of the community itself. However, interactions vary in strength, and it is clearly as important to measure the relative strength of an interaction as to merely document its presence.

The study of multiple species interacting simultane-
Figure 1. Interaction webs demonstrating three types of indirect interaction: (a) apparent competition; (b) predator-mediated competition; and (c) trophic cascade, as well as (d) a more realistic, species-rich interaction web depicting the major interactors associated with fireweed at Mt. St. Helens, in Washington.

Previously has led to the recognition that indirect effects can be important determinants of community structure, and several distinct types of indirect effects have been distinguished. For example, apparent competition occurs when two species appear to be competing because, as the population of one species grows, the abundance of the other declines. However, these changes in abundance are not caused by direct competition, but rather by a third species that consumes each prey species in proportion to its relative abundance (see Fig. 1a). A second type of indirect interaction occurs when a consumer species indirectly affects a species via its competitor. For example, a consumer that limits a competitively dominant species may indirectly benefit a competitively inferior species (see Fig. 1b). A third type of indirect effect thought to be common and important is a trophic cascade. An example of a trophic cascade is when a carnivore species limits the abundance of herbivores, resulting in luxuriant plant growth (see Fig. 1c). The presence of a trophic cascade is demonstrated when removal or exclusion of the carnivore results in a dramatic increase in the herbivore population and the subsequent decimation of plant biomass. Field studies are increasingly documenting the ubiquity and importance of indirect interactions. However, the difficulties encountered when studying the simplified food webs depicted in Figs. 1a–1c are greatly exacerbated when trying to understand the interactions occurring in more realistic, species-rich food webs (see Fig. 1d). The significance of this is that simple ecological experiments that focus on just one or two species may fail to reveal the important determinants of community structure.

In sum, theories of species interaction have largely focused on the problem of coexistence or, as it has also been called, the paradox of diversity. These theories address how so many species manage to coexist in nature, whereas simple lab experiments and mathematical models so often predict extinction. A major shift in thinking about this problem was the recognition that natural populations are subjected to environmental variability and other disturbances that can prevent the process of competitive exclusion. In addition, the complexities of multispecies interactions, including indirect interactions, can promote the coexistence of species.
Although the earliest models of species interactions seem abstract and disconnected from reality, ecology has a rich tradition of using experiments to test models. For example, the Russian biologist G. F. Gause pioneered the testing of species-interaction models using laboratory cultures of protozoans and yeast in which he could follow population dynamics on the time-scale of weeks, and thus could rapidly see whether or not a species could persist in his experimental systems. When examining competition between Paramecium species, Gause often observed that some species could drive others to extinction, a process termed competitive exclusion (and a result predicted in theory by the differential equations that depict continuous reproduction of two protozoans in competition for the same resource). Currently, laboratory microcosms involving protozoan communities are receiving fresh attention—nowadays these experiments are aimed at testing models of multispecies interactions and interaction webs.

IV. THEORIES OF BIODIVERSITY

Biodiversity is the variety of all living things, and most commonly refers to the number of different species in a particular area. Ecologists have documented striking patterns in the number of species occurring in different regions of the planet. For example, for most groups of species, there is a strong gradient of declining diversity from the equator to the poles, and the vast majority of species are therefore concentrated in tropical and subtropical regions.

Ecologists have proposed a variety of mechanisms that may be responsible for generating global patterns of biodiversity. For instance, areas with more varied landscapes and more topographic relief tend to support more diverse species assemblages than more uniform areas. Thus, spatial heterogeneity is likely to provide more ecological niches for species to occupy and therefore allow more species to coexist. As discussed earlier, classic ecological theory predicts that competitive interactions among species should lead to competitive exclusion and therefore reduced biodiversity. Several of the proposed mechanisms for global diversity patterns focus on forces that counter the process of competitive exclusion. Accordingly, it has been hypothesized that tropical regions harbor many species because their benign climate favors diseases and predators—these predators and diseases increase species diversity by attacking competitively superior species, thereby allowing weak competitors an escape from competitive exclusion. Disturbance is thought to similarly preclude competitive exclusion, although disturbance that is too intense or that occurs too frequently may result in reduced biodiversity. The idea that diversity should be reduced when disturbance is either too rare or too frequent has been termed the intermediate disturbance hypothesis.

Another robust pattern of biodiversity is the observation that islands generally have fewer species than mainland, and that larger islands tend to have more species than smaller islands. R. H. MacArthur and E. O. Wilson proposed the equilibrium theory of island biogeography to account for this pattern. According to this theory, there is a balance between colonizations of new species on islands and the subsequent extinctions of established species. On larger islands, colonizations are relatively more frequent and extinctions are less frequent, resulting in a higher equilibrium number of species on larger islands.

Human activities such as the direct harvesting of species, introductions of alien species, habitat destruction, and various forms of habitat degradation have greatly accelerated the loss of biodiversity. Consequently, current extinction rates are estimated to be 100 to 1000 times higher than pre-human extinction rates. This extinction crisis has spurred a great deal of scientific interest in the biological and ecological functions of biodiversity. Organisms are responsible for a variety of ecosystem functions, including maintenance of the gaseous composition of the atmosphere, regulation of the global climate, generation and maintenance of soils, and recycling of nutrients and waste products. However, it is not obvious whether these biological services require many species or only a handful of species. Much current research is focused on understanding how much (if any) diversity we can afford to lose yet still maintain the necessary ecosystem functions (see Section VII).

Some species play obviously important roles in ecosystems—the addition or deletion of these "keystone" species leads to dramatic changes in ecosystem functions such as productivity or nutrient uptake. However, most species probably do not exert such important effects on ecosystems. In other words, it may be possible to lose a number of species from an ecosystem without little overall impact on ecosystem function. This could be the case if several species that perform approximately the same function are present in the original ecosystem. The situation where multiple species play a similar role has been termed "species redundancy." If species redundancy is a common phenomenon, ecosystem function should be largely independent of species diversity, so long as major functional types are represented. Thus, when one species is lost from an ecosystem, some other
species with a similar function may become abundant and compensate for the lost species, leaving the ecosystem as a whole relatively unaffected. Indeed, ecosystem processes often do remain stable despite large fluctuations in the abundance of the various species involved. The term species redundancy may seem to imply that all species are not necessary for an ecosystem to function properly. However, species redundancy may in fact be an essential feature for the long-term health of ecosystems, and the importance of any particular species may only become evident during the occurrence of rare, drastic events.

V. SPATIAL PATTERNS

Spatial patterns and habitat patchiness or heterogeneity have spawned a host of concepts that try to both describe these spatial patterns and explain their impacts and sources. The two most important general results of spatial theory in ecology are:

1. The fact that species interact in spatially extensive and patchy worlds creates opportunities for persistence and coexistence of species that would otherwise not exist.

2. In uniform environments, the interplay of dispersal and nonlinear population dynamics can produce complex spatial patterning in population densities, and this patterning can itself promote coexistence in predator–prey or competitive interactions.

More generally, spatial theory emphasizes that it may be impossible to understand ecological processes and interactions if the focus and scale of a study is too small. This is an important caution, given the fact that many experimental ecology studies are conducted at scales of less than 1 m2.

One of the most important practical applications of spatial theory stems from the use of metapopulation models in conservation biology. Metapopulation theory describes a species as a collection of populations (or patches) in which there is turnover due to local extinction and subsequent recolonization by dispersing individuals, and in which the fate of a species can only be understood by tracking the fate of a collection of populations or patches, as opposed to a single local population or patch. Metapopulation models are of considerable importance in conservation applications because they identify critical thresholds for habitat destruction or for the creation of barriers to plant and animal dispersal, thresholds that, once crossed, imply doom for a species (because colonization becomes too infrequent to counterbalance local extinctions). It is obvious to anyone who has looked out an airplane window that one of humankind’s major impacts on the world is to destroy habitats and to create ever more fragmented landscapes dissected by highways, agricultural fields, and commercial or residential developments that surely hinder the dispersal of species. If this trend proceeds too far, metapopulation theory predicts the slow but inexorable loss of species. Spatially detailed models of human-modified landscapes are increasingly being used to identify strategies for land use and human development that will minimize the undesirable effects of habitat loss and habitat fragmentation. The two most common strategies involve clustering of habitats and the protection of dispersal corridors.

At a more theoretical level, spatially explicit models of species interactions indicate that the interactions themselves can result in pattern formation. For example, high rates of predation combined with limited prey dispersal can result in a dense patch of prey surrounded by a zone that is relatively devoid of prey due to intense predation. This “ring” of intense predation can limit the spread of prey populations. It is important to realize that these spatial patterns can emerge without any underlying environmental heterogeneity. Spatial patterning can allow more species to coexist because the species occupy different portions of the pattern. However, the opportunity for spatial segregation of species into different characteristic portions of spatial patterns requires sufficiently large habitats—if habitats are carved into patches that are too small, patterns cannot be generated, and opportunities for coexistence will be lost. Thus, theories of pattern formation reveal yet another mechanism by which biodiversity can be maintained, and conversely a route by which biodiversity can be degraded.

VI. SCALING LAWS

Because ecological processes operate across a huge range of scales, there have been numerous attempts in ecology to identify scaling laws—laws that allow us to study phenomena on one scale and predict those same phenomena at different scales. Just as important as identifying rules for extrapolating across scales is the idea that there are critical spatial scales at which scaling laws break down and processes fundamentally change in character.

An especially good example of successful extrapolation across scales concerns the prediction of the rate at
which exotic species invade new areas and expand their ranges. Simple invasion models extrapolate short-term observations of dispersal (over the scale of one year or less and involving the movements of single individuals) to the broad expanse of an entire species range after decades and over thousands of kilometers. For organisms as diverse as muskrats and cabbage butterflies, invasion models have successfully used small-scale and short-term data to predict long-term rates of range expansion.

To quantitatively examine the legitimacy of extrapolations across scales, it is often useful to graph the variance of a measured variable as a function of the spatial scale at which it was measured. For example, population density could be measured in anything from 1-m² quadrats to hectare plots, and the variance in density (per unit area) among plots is expected to decline with increasing plot size. The rate of this decline is a measure of spatial correlation. However, marked changes in the slope relating variance in population density to measurement scale indicate some fundamental shift in biological processes—such as a shift from patterns generated by the dispersal range of a plant’s seeds to patterns generated by large-scale climatic heterogeneity. Such nonlinear relationships between variance and scale indicate circumstances where it may not be appropriate to extrapolate across scales.

Most ecologists continue to conduct research at one and only one scale. Although theories regarding scaling laws are still in their infancy, they plainly draw attention to the fact that any extrapolation across scales is tenuous, and can only be justified if the processes have been studied or measured at more than one scale.

VII. ECOSYSTEM THEORIES

Ecosystem theories focus on patterns of energy flow, nutrient cycling, and the factors that control or limit the rates of these processes and the stability or predictability of these processes through time. To assess the flow of energy and nutrients, it is useful to recognize that organisms fill different trophic roles: autotrophs (usually plants) acquire energy, usually from the sun, and nutrients from nonliving materials; heterotrophs derive energy and nutrients by consuming living matter, and decomposers transform once-living materials back to their inorganic forms. Both nutrients and energy flow from autotrophs to heterotrophs and decomposers, and the connections among these groups, constitute a food chain or food web.

The trophic interactions among species affect the rates of ecosystem functions, including biogeochemical processes, the flow of nutrients, water, and atmospheric gases, and the processing of energy through ecosystems. Species are the key working parts of ecosystems, and therefore biodiversity must be related in some way to ecosystem function. Certainly ecosystems would not function if all species were lost, but it is unclear just how many species are necessary for an ecosystem to function properly. The current extinction crisis has prompted ecologists to assess the relationship between biodiversity and various ecosystem properties. Evidence regarding the importance of biodiversity for ecosystem function largely comes from comparing ecosystems that naturally differ in the number of species present. More recently, ecologists have undertaken more controlled manipulative experiments in which the number of species has been directly varied. Several studies have demonstrated that various measures of ecosystem function, such as production of biomass and nutrient uptake, increase as the number of species present increases. However, some studies also report no effect or even negative relationships between biodiversity and ecosystem processes.

Although some evidence suggests that biodiversity increases or improves the overall functioning of ecosystems, the underlying mechanisms remain unclear. For example, a positive relationship between species diversity and productivity could result simply because including more species increases the chance of including particularly productive, or fast-growing, species. Alternatively, a diverse group of species may use the available resources more efficiently, because each species has a slightly different strategy, resulting in higher overall growth.

A second commonly purported benefit of biodiversity is that more diverse ecosystems may be more stable compared to species-poor ecosystems. Stability can be defined at the community level as fewer invasions and fewer extinctions, meaning that a more stable community will contain a more stable composition of species. However, stability can also be defined at the population level as reduced fluctuations in population size, meaning that a more stable population will contain a more constant number of individuals.

The idea that biodiversity confers stability to ecosystems has enjoyed a long and controversial history. Ecologists initially hypothesized that diverse ecosystems were more stable than those with fewer species because, it was reasoned, with more species in an ecosystem, there are more paths through which energy and nutrients can flow. Consequently, in diverse ecosystems each species should be less affected by changes in the abun-
dance of other species, leading to higher overall stability. However, mathematical models exploring the relationship between biodiversity and population stability indicated that higher species diversity generally reduces the stability of population dynamics of individual species. The conflict between these modeling results and the original intuitions of ecologists remained unresolved for many years.

Recent experimental manipulations of species diversity have helped to resolve this long-standing controversy. In particular, several manipulations of plant and microbe diversity have been performed to examine the stability of various measures of ecosystem function over time. Generally, such studies have shown that, although the abundance of individual species fluctuates more dramatically in high-diversity ecosystems, the total abundance or productivity of all species combined is actually more stable. These empirical results are consistent with both views of diversity and stability. First, the fact that individual species fluctuate more in diverse systems supports the results of mathematical models regarding diversity and stability. On the other hand, the observation that aggregate attributes such as productivity become more stable with increased diversity supports the intuition that multiple pathways for energy (high diversity) foster stability.

Although the relationship between biodiversity and ecosystem stability is becoming increasingly clear, the mechanisms generating this pattern are not. In particular, diverse groups of species may be more stable because complementary species compensate for one another. Alternatively, variation in aggregate measures such as total productivity may increase with richness due to averaging of random fluctuations in the growth of each species. On the basis of simple probability theory, it is expected that as more independently varying species are summed together, the more stable will be the sum of their abundances. The strength of this averaging effect depends on correlations among the species' fluctuations, but a positive relationship between biodiversity and the stability of aggregate measures of ecosystem function should almost always be expected, simply due to averaging.

VIII. EVOLUTIONARY THEORY IN ECOLoGY

Evolutionary theory has entered ecology in two major areas: the evolution of species attributes and how they might vary in a predictable manner, and the coevolution of interacting species, such as the evolution of virulence and resistance in host–pathogen interactions.

There is often a remarkable matching between the traits of organisms and the local conditions in which they live. Ecologists and population geneticists alike have worked to identify the factors contributing to or preventing the adaptation of populations to various aspects of their local environments, including food sources, predators, and microclimatic conditions. Reciprocal transplant and common garden experiments have been the major tools used to test for local adaptation. In particular, there is interest in the balance between selection for locally adapted traits and the immigration of individuals with nonadapted traits into the population. This balance between differentiating selection and the homogenizing effects of migration can create a difficult conundrum for conservation biologists—for a rare species that exists in several small populations, it might be better to pool all the individuals together to bolster the size and viability of a single population. Alternatively, the subpopulations might be so genetically distinct and locally adapted to their environments that pooling the individuals might actually harm the species. Thus, one of the more difficult challenges in conservation is to balance the short-term viability of a species with preservation of its long-term evolutionary potential.

As a species evolves to become locally adapted to other species in its environment, it can exert selection pressure on the co-occurring species, leading to changes in the traits of these species with which it interacts. The reciprocal evolution of two species in response to one another is called coevolution. The term coevolution was originally coined to describe the presence of toxic compounds found in plants and the ability of butterfly species to detoxify these compounds. Indeed, many of the best-known examples of coevolution involve reciprocal changes between adversaries, a sort of ever-escalating "arms race" as might occur between a predator and its prey or between a parasite and its host.

Plant breeders try to directly manipulate the coevolutionary process that occurs between crop plants and the herbivores and pathogens that attack these plants. Selective breeding is used to maximize the defenses naturally present in crop species and, more recently, genetic engineering has allowed breeders to co-opt defenses of very distantly related organisms and introduce completely novel defense traits to crops. Unfortunately, when highly defended crops are planted over the enormous spatial scales of modern farms, herbivore and pathogen species tend to quickly evolve resistance to the plant defenses. Thus, an important application of
evolutionary ecology involves determining how we can best deploy plant defensive traits such that evolution on the part of plant pathogens and herbivores does not make the plant defenses obsolete. Theory suggests that alternating plantings of crops with distinct defensive traits may reduce the ability of herbivores to evolve resistance. In addition, incorporating combinations of defensive traits into single individuals should substantially reduce the likelihood that herbivores will become resistant. Thus, theory in evolutionary ecology has contributed concrete strategies that could greatly enhance the “longevity” of plant defenses, with enormous economic consequences.

IX. SYNTHESIS

Of the numerous specific concepts and theories discussed in this article, some general ideas emerge that relate pattern to process and dynamics to structure. First, complicated spatial or temporal patterns in population densities do NOT require environmental explanations or complicated underlying dynamics—rather, we should expect patterning, cycling, and complexity simply because of the feedbacks inherent in ecological systems. This is of more than theoretical interest, because it implies that any management of ecological systems must heed the implications of nonlinear dynamics. In other words, we must anticipate that rates of change in population growth or in number of species may change dramatically and suddenly, not just because of random fluctuations in the environment, but also as a result of deterministic processes. Second, several ecological models, including epidemiological and metapopulation models, point to critical thresholds across which systems change qualitatively (e.g., a disease can no longer persist, or a population dwindles toward extinction because colonizations fail to balance local extinctions). Third, opportunities for coexistence of species arise whenever the world in which organisms live becomes less uniform—spatial heterogeneity creates refugia, disturbances interrupt the process of competitive exclusion, and so on. In contrast, human actions tend to enforce regularity and control on the natural world, and ecological theory suggests that this homogenization of nature is contributing to the erosion of our planet’s biodiversity. The consequence of this reduction in biodiversity remains an open theoretical question, with the greatest challenges to ecological theory being the development of models that contend with rich webs of species interactions in complex ecosystems. The future of ecological theory lies in blending human activities with natural processes, so that we can better understand how to encourage a sustainable biosphere while accommodating human interests and demands.

GLOSSARY

polyculture Growing two or more crops in the same field at the same time.
resilience The rate at which an ecosystem returns to original conditions after a perturbation.
resistance The degree to which an ecosystem changes in response to a perturbation.
transgenic crop Crop whose genome contains a gene(s) from a distinct species that has been inserted by genetic engineering.

THE POPULARITY OF AGRICULTURE as a focus of ecological study has waxed and waned during the past century. Agricultural systems have been touted as model systems for testing ecological theory because of their relatively well-characterized components, simple food webs, and manipulability. In the past, they have often served as effective model systems for plant ecology, plant-insect interactions, and predator–prey theory. In recent years, the growth of sustainable agriculture has resulted in increasing interest in understanding ecological processes in agriculture so that they can be manipulated more effectively for enhancing agricultural productivity and reducing negative environmental impacts of agricultural activities. A variety of types of ecological theory have been applied to agricultural systems, and thus the subdiscipline of “agroecology” encompasses a very broad range of approaches, including physiological ecology, population biology, community ecology, ecosystem ecology, and landscape ecology. All these approaches offer significant insights into the ecology of agricultural systems and provide useful guidelines for improving the functioning of these systems. Because the role of diversity in ecological systems has been a consistent element in much agroecological research, this article focuses on diversity in agricultural systems, with particular attention to areas of agroecology that appear to have the most potential to offer agricultural and environmental enhancement.

I. PLANNED AND UNPLANNED DIVERSITY IN AGROECOSYSTEMS

The biodiversity in agroecosystems can be classified as either "planned" or unplanned diversity. Planned diversity includes the spatial and temporal arrangement of domesticated plants and animals that farmers purposely include in the system. It may also include bene-
ficial organisms that are deliberately added to the agroecosystem, such as biological control agents or plant-associated nitrogen-fixing bacteria. Unplanned diversity includes all the other associated organisms that persist in the system after it has been converted to agriculture or colonize it from the surrounding landscape. This component of diversity is likely to include a variety of herbivores, predators, parasites, and microorganisms that make up the majority of species in any ecosystem, even a simplified one such as an agroecosystem. It has become increasingly clear that the two components of diversity are significantly linked: As planned diversity increases, the diversity of the associated biota also increases. Although the evidence for the plant-based food web is strongest, this relationship also appears to exist for the detritus-based food web.

Given this relationship between planned and unplanned diversity, how do both types of diversity influence agricultural productivity and other ecological processes that occur in and around agroecosystems? The impact of planned diversity is relatively well understood, but much remains to be elucidated about the role of unplanned diversity in agroecosystem function.

II. IMPACT OF PLANNED DIVERSITY ON ECOLOGICAL PROCESSES

Agroecosystems vary dramatically in their complexity and degree of planned diversity, and planned diversity may include genetic diversity, species diversity, structural diversity, and functional diversity (Fig. 1). The input-intensive monoculture systems that dominate commercial agriculture worldwide have low planned diversity and relatively simplified community assemblages. At the other extreme, traditional agricultural systems and home gardens of the tropics typically have extremely high planned diversity and complex assemblages of associated biota. This range of planned diversity in existing systems has provided rich opportunities for exploring the impact of planned diversity on a suite of ecological processes, including primary production, pest regulation, decomposition, and nutrient cycling.

A. Planned Diversity, Productivity, and Stability

The idea that diversity should impart stability to ecological systems, including agricultural systems, dates back at least to the 1950s and has stimulated much ecological theory, some empirical research, and extensive debate. Until recently, the best evidence for the idea that diverse systems should be more stable than simple ones came from agricultural ecosystems rather than natural ecosystems. Many agricultural studies have demonstrated increased productivity (i.e., significant yield increases) in diverse cropping systems compared to monocultures. However, the majority of these studies address systems of relatively low plant species richness, comparing monocultures to polycultures of two or three species. We expect that the relationship between productivity and plant species richness should resemble the asymptotic curve in Fig. 2, as it appears to do for natural grasslands (Tilman et al., 1996), but we have little data to indicate where the asymptote might be. Researchers have speculated that the increase in productivity with increasing species richness in agroecosystems may level out at approximately 10 plant species, although this

FIGURE 1  Degree of different types of planned diversity found in some typical agroecosystems. Intensity of shading indicates degree of diversity.
The tendency of diverse cropping systems to have higher productivity than would be expected on the basis of the productivity of their component crops grown in monoculture is often called "overyielding." Overyielding may result from a variety of mechanisms, such as more efficient use of resources (light, water, and nutrients) or reduced pest damage, and there have been numerous experimental studies examining these mechanisms. When interspecific competition for a limiting factor is less than intraspecific competition for that factor, overyielding is predicted. Facilitation occurs when one crop modifies the environment in a way that benefits a second crop. For example, by lowering the population of a critical herbivore or releasing nutrients that can be taken up by the second crop. Facilitation may result in overyielding even where direct competition between crops is substantial (Vandermeer, 1989).

There is evidence that diverse cropping systems exhibit greater yield stability and higher productivity, suggesting that resistance to environmental perturbation may be higher in diverse systems. Yield stability has been measured in at least three ways: by calculating coefficients of variation of yield, by computing regressions of yield against an environmental index, and by estimating the probability of crop failure. Polycultures exhibit greater yield stability according to all criteria. Polycultures tend to have lower coefficients of variation than crops grown as separate monocultures, the response of polycultures to environmental change tends to be as stable or more stable than the most stable component crop grown in monoculture, and polycultures tend to have a much lower probability of crop failure than the component crops grown in monoculture. The probability of crop failure is an estimate of risk and lower probabilities result from both the higher yields of polycultures and the putative yield stability. Overall, studies indicate that diverse cropping systems are more stable than monocultures, both agronomically and economically.

Several mechanisms may lead to greater yield stability in diverse systems. When one crop performs poorly because of drought or pest epidemic, for example, the other crop(s) can compensate, using the space and resources made available. Such compensation is obviously not possible if the crops are grown separately. If the yield advantages of polycultures are greater under stress conditions, then yield stability is higher. This polyculture advantage has been demonstrated for crops under nutrient stress and drought stress. Moreover, where polycultures lead to reduced pest attack, as they often do, then greater yield stability may result from the dampening of pest outbreaks and disease epidemics.

These processes may operate simultaneously in diverse systems and are consistent with the idea that species richness buffers productivity under conditions of environmental variability and that diversity imparts resistance to perturbation. The ability of polycultures to compensate for losses might also be considered to represent resilience. Whereas systems with greater resistance will be less impacted by a perturbation, systems with greater resilience return rapidly and reliably to original conditions.

As a result of this evidence that diverse cropping systems often have greater productivity and stability, there is a persistent conviction among many agroecologists that species-rich natural ecosystems should provide us with models for the design of sustainable agricultural systems. Jackson (1985) and colleagues at the Land Institute in Salina, Kansas, have promoted the idea that agriculture in the U.S. plains should mimic natural prairies by emphasizing polycultures of herbaceous perennials. Others have noted the structural and functional similarity between diverse home gardens in the tropics and humid tropical forests and have suggested that agricultural systems for the tropics should be designed as analogs of natural tropical forests.

Ecological research on the role of diversity in natural grassland systems by Tilman and colleagues (1996) indicates that diverse natural communities may be more productive than simple systems, at least partially as a result of increased nitrogen use efficiency in more diverse systems. These studies also suggest that more diverse plant communities are more resistant to disturbance and more resilient in the face of environmental perturbations such as drought. That is, the productivity of diverse communities appears to decline less during a drought and to return more quickly to predrought
levels than is the case for species-poor communities. It remains to be seen, however, whether the "natural systems mimicry" approach can really lead to useful improvements in the productivity and sustainability of agroecosystems.

B. Planned Diversity and Pest Regulation

The planned diversity of the agroecosystem has important effects on herbivorous insects and the microbial community attacking crops. Traditional agricultural systems often include substantial planned genetic and species diversity, and genetically diverse grain crops are used in many parts of the world to control pathogens. In contrast, the low planned diversity of most commercial monocultural systems often results in large crop losses from a pest complex that is less diverse but more abundant than that in more diverse systems. The trend for higher pest densities in monocultures compared to diverse cropping systems is especially strong for specialist insect herbivores with a narrow host range. As planned diversity increases, population densities of these specialist herbivores decrease.

In a classic paper, Root (1973) offered two hypotheses to explain higher densities of herbivorous insects in simple, monocultural systems: the resource concentration hypothesis and the enemies hypothesis. The first hypothesis predicts that herbivores, particularly specialists, in pure, dense host plant stands will be more likely to find their hosts and more likely to survive and reproduce. In contrast, herbivores in less dense or more host plant-diverse stands should be less likely to find their hosts and more likely to lose them. Although the details of herbivore-host interactions vary considerably, subsequent experimental tests of this hypothesis have generally supported it with respect to the effects of diversity, especially for specialist herbivores. Host-finding behavior and insect movement, both colonization and emigration, appear to play important roles in the response of herbivorous insects to agroecosystems. Densities of specialists may be lower in diverse systems because (i) they have difficulty locating hosts due to interference with olfactory or visual cues or (ii) they leave hosts more often due to lower plant quality and then have difficulty relocating them. These behaviors are significantly affected by the chemical, nutritional, and structural diversity that accompanies planned plant species diversity.

The enemies hypothesis predicts that diverse systems should have higher densities of herbivore natural enemies (predators and parasites) because they provide more resources for these natural enemies, such as alternate prey or hosts, nectar, pollen, and refugia. This hypothesis has also largely been supported in experimental studies. Compared to monocultures, diverse systems are likely to have higher predation rates, higher parasitism rates, and higher ratios of natural enemies to herbivores, all of which may contribute to lower pest densities. Natural enemies comprise one component of the unplanned diversity that increases as planned diversity increases in agroecosystems.

Microbial pathogens also respond to the planned diversity of agroecosystem, but their response is more variable than that of herbivorous insects. Crop diversification can modify the microclimatic conditions that play an important role in the development and severity of plant disease. Pathogen growth and reproduction may be either encouraged or inhibited in more diverse cropping systems, depending on the particular requirements of the organism. The effects of diversity depend on a variety of dispersal processes, infection efficiency, and the rate of disease progress. The majority of viruses, however, are transmitted by insects, and these tend to be found at lower incidence in diverse systems due to the effects of plant species diversity on their insect vectors.

The genetic diversity of crops can dramatically reduce pathogen impacts on crop productivity. Mixtures of genotypes of a single species, such as multiline cultivars and varietal mixtures, have been used effectively to retard the spread and evolution of fungal pathogens in small grains and other crops. There is evidence that they may also have lower densities of insect herbivores and a lower incidence of plant viruses. Typically, these mixtures include both resistant and susceptible crop genotypes, although they may be mixtures of several different resistant genotypes. The reduction in pathogen spread is greater than would be expected on the basis of the proportion of resistant genotypes in the mixtures, and therefore it appears to be due to the effects of diversity per se on the ability of pathogens to disperse.

High planned diversity that includes genetic diversity, species diversity, and structural diversity thus has a strong influence on populations of herbivorous insects and plant pathogens. The intentional manipulation of planned diversity for the purpose of pest control is common in traditional agricultural systems, and it offers real potential for increasing the productivity of contemporary agricultural systems without the negative environmental impacts of pesticides.

C. Planned Diversity and Soil Processes

Planned diversity may also have significant impacts on the soil community. Plant pathogens and their antagonists in the soil are well-known to respond to crop
diversity. Long-term, continuous monoculture can result in dramatic shifts in the competitive balance among microbial species and increase the aggressiveness of plant pathogens. Conversely, populations of plant parasitic fungi, bacteria, and nematodes may decline when monocultures of their host plants are replaced by diverse cropping systems. Rhizosphere microbial communities, including a variety of bacteria and fungi, respond to plant species composition of the cropping system, plant phenology, plant nutrient status, and even plant genotype. Plant mutualists such as mycorrhizal fungi or nitrogen-fixing bacteria may be strongly determined by crop composition and phenology. Some ecological processes such as nitrogen cycling may be substantially controlled by crop diversity and plant composition since the inclusion of legumes can increase rates of biological nitrogen fixation. Due to the effects of litter diversity, decomposition rates may also be quite responsive to planned diversity.

Despite an increasing awareness of the effects of planned crop diversity on the soil community, our ability to predict the impacts of manipulating planned diversity is limited because our understanding of the complex interactions among soil organisms and between plants and soil microbes is still rather weak. Greater attention to the ecological dynamics of these soil communities under different cropping systems will aid in determining the extent to which we can manage these communities to enhance agricultural productivity using planned diversity.

III. UNPLANNED DIVERSITY AND ECOLOGICAL SERVICES

The unplanned diversity that accompanies planned diversity in agricultural systems can provide many ecological services to agriculture. This means that the conservation of biodiversity can offer significant benefits to agriculture. Uncultivated species, including wild relatives of crops that occur in and around the agroecosystem, are an important source of germplasm for developing new crops and cultivars. Increasing planned crop diversity can augment the resources available to pollinators and to natural enemies such as parasitic wasps, resulting in higher populations of these beneficial organisms. Increasing planned diversity may also foster beneficial soil organisms and the conservation of functional processes, such as decomposition and nutrient cycling.

Overall, unplanned diversity within the agroecosystem affects plant and soil processes that can in turn affect crop productivity. For example, many traditional cacao and coffee systems in the tropics resemble forest ecosystems since they are well shaded and humid, with a diversity of shade trees, a diverse herbaceous understory, and a thick leaf litter layer. Thus, these traditional agroecosystems have high planned species diversity, high genetic diversity, and high structural diversity. Recent studies have shown that shaded cacao and coffee plantations support higher levels of biodiversity than full-sun plantations grown without shade trees, i.e., monocultures (Perfecto et al., 1996). The shaded systems may be traditional “rustic” systems in which the understory of native forests is cleared and the crop is planted under the natural forest overstory. They may also be improved systems in which a few carefully chosen tree species are planted interspersed among the crop. In either case, these shaded systems have high planned diversity accompanied by high unplanned diversity.

Shaded coffee and cacao have been demonstrated to be good habitats for migrant and resident forest birds in the neotropics, and these birds may be important consumers of pest insects. They also contain relatively high diversities of insects, lizards, and other fauna, some of which contribute to pest regulation. Pollination also appears to be enhanced in shaded systems. Since many of the commonly used shade trees are leguminous, the trees reduce the amount of nitrogen inputs required. In addition, the shade provides significant weed control and, at least in cacao, reduces the incidence of several important diseases. The high levels of unplanned diversity thus contribute significantly to agricultural productivity. Moreover, by serving as habitat for a relatively high diversity of vertebrate and invertebrate animals, such agroecosystems may enhance the conservation value of a agricultural landscape.

A. Unplanned Diversity and Pest Regulation

One of the ecological services provided by the unplanned diversity in agroecosystems is the regulation of herbivorous insects and microbial pathogens by competitors, predators, and parasites. As discussed previously, high planned diversity often results in higher densities of predators and parasites. Even in agroecosystems of low planned diversity, the diversity of natural enemies may be quite high as long as pesticides are not used. For example, paddy rice monocultures managed without pesticides can have surprisingly high diversities of herbivorous insects, predators, and parasitoids compared to similar monocultures in which pesticides are used. Recent pest management programs in Southeast
Asian paddy rice have taken deliberate advantage of this diversity and drastically reduced pesticide inputs without sacrificing yields. In traditionally managed rice fields, the predators are likely to include fish and amphibia, which contribute to pest regulation and also provide additional nutritional resources for farm families.

B. Unplanned Diversity and Soil Processes

Despite some significant advances in our understanding of soil processes, we know relatively little about the soil biota and their impact on agricultural productivity. In natural ecosystems, decomposition and soil nutrient cycling are regulated by a diverse community of invertebrates and microorganisms, such as termites, earthworms, nematodes, fungi, and bacteria. The composition, abundance, and activity levels of the soil biota in agricultural systems are markedly different from those in surrounding natural ecosystems. For example, the diversity and abundance of soil insects and earthworms in tropical agroecosystems are typically significantly reduced compared to those of a wide range of undisturbed tropical ecosystems. In cases in which abundance remains high in agricultural systems, the soil communities are often dominated by a single or small number of species highly adapted to the modified environment.

The changes in the soil community under agriculture result from a variety of perturbations to the soil environment. The initial conversion from undisturbed ecosystems typically involves the removal and/or burning of plant biomass followed by tillage—activities which have drastic impacts on soil structure and soil chemistry. The physical changes at the soil surface amplify diurnal and seasonal fluctuations of temperature and moisture. In addition, organic inputs to the soil are significantly reduced as a result of plant biomass removal, and the chemical composition of organic inputs is altered. These extreme modifications of the soil environment can result in the elimination of some soil organisms and, at a minimum, are likely to change the competitive balance among species. To the extent that agricultural systems minimize these perturbations (e.g., by reducing tillage or burning), the impacts on the soil community may be less severe.

Despite these well-known effects of agricultural conversion on the soil community, the link between loss of soil biodiversity and various ecological processes has not been extensively studied. Decomposition and nutrient mineralization, for example, are controlled by the activities of a diverse community of organisms. It is not clear that the loss of some species will result in significant changes to these functions, but the degree of functional redundancy among different species is still controversial. On the other hand, some processes such as nitrogen fixation are carried out by very specific organisms, whose loss might substantially affect nitrogen cycling. Given the importance of soil biota for decomposition and nutrient cycling, it is essential that the link between this component of unplanned diversity and function be explored more fully.

IV. IMPACTS OF AGRICULTURE IN THE LANDSCAPE

Ecological concepts have often been utilized to address the consequences of agricultural perturbations for natural ecosystems in agricultural landscapes. For example, the impacts of nutrient inputs and pesticides for downstream aquatic and terrestrial ecosystems have been well studied. Much of the pesticide applied to crops fails to reach the target pests and instead moves into adjacent ecosystems, where it can have significant impacts on the diversity and abundance of nontarget species. Studies have shown that pesticides have strong effects on trophic dynamics and a range of ecosystem processes in complex natural ecosystems, both aquatic and terrestrial. Similarly, movement of nitrogen from agroecosystems to natural ecosystems through leaching or deposition may lead to significant impacts at several trophic levels. Increased nitrogen loading may reduce plant species richness while increasing the biomass of dominant species. In response to these changes, both pathogens and herbivorous insects are likely to exhibit lower species richness but higher population abundance, just as they do in agricultural systems. Changes in pathogen and herbivore populations may in turn influence the productivity and fitness of their host plants. Even in the absence of changes in herbivore population pressure, research has shown that the effects of herbivory on plant growth and reproduction may be more severe at high levels of nutrient availability. As with the complex effects of pesticides, these impacts of inadvertent fertilization are likely to impact trophic dynamics and ecosystem processes.

A. Ecological Risks of Genetically Engineered Crops

In general, the impacts of agricultural technologies such as pesticides and chemical fertilizers were characterized many years or decades after the introduction of the technology and well after their use was widespread.
In contrast, ecologists began to call attention to the ecological consequences of genetically engineered crops before these crops were widely available commercially. In the past few years, however, these transgenic crops have rapidly become common in agricultural systems throughout the world, but the ecological impacts of these crops are still poorly understood. Many ecologists throughout the world are beginning to investigate these impacts in order to develop a realistic assessment of the potential risks to the ecology of both natural and agricultural ecosystems. Despite the relatively small number of studies undertaken to date, this research is having an important influence on how transgenic crops are being deployed.

Ecologists are investigating many different types of risks, including changes in the ecological competency of the crop, transgene movement from crops to wild relatives, the evolution of resistant pests, risks to non-target organisms, recombination between genetically engineered plants expressing virus resistance and natural viruses leading to new viral genotypes, and changes in crop management strategies and cropping systems. These different types of risk are receiving differing degrees of attention from ecologists.

There is evidence for changes in the ecological competency of a few crops. Through genetic engineering, the crop may acquire particular traits that allow it to survive better in natural ecosystems or as a volunteer in agricultural systems. Such traits might include seed survival, increase crop resistance to pests or diseases, or increase the competitiveness of the crop relative to wild plants. This process could lead to invasion of natural ecosystems and ecological disruption. In addition, genetically engineered traits such as herbicide resistance can make volunteer crops persistent weeds in subsequent cropping systems. This problem has already been detected with canola (rapeseed) that has transgenic herbicide resistance.

Genetically engineered traits may also move from crops to wild relatives of crops through natural processes of gene flow and hybridization. Many recent studies have examined the degree of hybridization between crops and wild relatives. Successful hybridization under natural conditions has been demonstrated for many crop–wild relative associations, and some studies have documented the persistence of crop genes in populations of wild relatives over several generations. Traits such as pest and disease resistance or herbicide tolerance may provide a selective advantage to wild relatives of crops and allow them to become weeds in agroecosystems or to increase in abundance in natural ecosystems and thereby disrupt natural patterns of plant distribution.

Increasingly, ecologists are exploring the possible effects of these transgenic crops on non-target organisms, including natural enemies and soil biota, and evidence for detrimental effects is accumulating. For example, lacewing predators fed on prey that consumed transgenic crops expressing Bacillus thuringiensis (Bt) toxins (bacterial insecticides) have higher mortality than those fed on prey that did not consume Bt toxins. Similarly, parasitic wasps that develop in Bt-treated host insects have higher mortality. Through the incorporation of crop residues into the soil, Bt toxins can accumulate in the soil and cause changes in the abundance and species composition of soil microorganisms, thus affecting decomposition and nutrient cycling.

There is much less work on the ecological implications of viral recombination, but recombination has been demonstrated several times between replicating natural viruses in host plants and transgenes that have been inserted into host genomes. It has been demonstrated that this recombination can lead to changes in viral competitiveness and pathogenicity to hosts. Recombination may also alter transmission characteristics and allow transmission by new species of vectors, which would augment the opportunities for virus establishment in new host species. Thus, the potential for ecological impacts of new, recombinant viruses arising from transgenic crops is significant and warrants more attention from ecologists.

V. FUTURE DIRECTIONS

Although the study of agricultural ecosystems has provided many insights into the role of diversity in agroecosystem function and the ecological impacts of agriculture, the subdiscipline of "agroecology" is still in its infancy. Two areas that urgently warrant more attention from ecologists are (i) the influence of planned and unplanned agroecosystem diversity on soil processes such as decomposition and nutrient cycling and (ii) the ecological consequences of widespread adoption of genetically engineered crops. A better understanding of the ecological processes operating in both areas could result in significant benefits to both agriculture and environmental protection.

I. Introduction
II. Net National Product
III. Environmental Kuznets Curves
IV. Technological Change and Growth Accounting

THIS ARTICLE DISCUSSES three questions: What is economic growth? Will economic growth deteriorate or improve the environment? and What is the role of environmental resources for economic growth?

I. INTRODUCTION

The title of this article has many meanings. Economic analysis of environment and growth can mean many different things. In this article, the focus is on the following issues:

• What is economic growth?
• Will economic growth deteriorate or improve the environment?
• What is the role of environmental resources for economic growth?

The first question is typically answered by growth in gross domestic product (GDP) or GDP per capita. However, seldom is it explained why this is an interesting definition of growth. Of course, behind this notion of growth is the notion that GDP or gross national product (GNP) is a measure of well-being in society. It is therefore necessary to discuss what we mean by well-being and possible indices for such a concept. This will, of course, immediately bring us to a discussion of green accounting. There is a huge literature on this subject, but in this article I will not try to survey those contributions but instead examine one particular formulation of the conceptual basis of green accounting in order to determine the difficulties in creating such an index.¹

The second question has during the past 10 years been discussed in terms of so-called Kuznets curves—that is, empirically estimated relations between environmental quality and GDP per capita. The general finding for many pollutants is that a country with a very low income does not have much pollution but when the scale of the economy grows, for example, as measured by GDP per capita, emissions of these pollutants will increase. However, when the income per capita is high enough, the economy will reach a turning point and pollution will decrease with further increases in per capita income. This has been taken by the World Bank to mean that growth implies a win–win strategy. By growing, a country may in the long run obtain both increased material well-being and a better environment. Of course, this kind of analysis has been criticized, from conceptual points of views and also from econometric and empirical points of view. Once again, the literature

¹ The discussion of these issues is based on Dasgupta and Måler (2000) and Måler (1999).
is huge, and no attempt to summarize this literature will be done. However, some central issues will be discussed.

Finally, the role of environmental resources as inputs for the growth process has very seldom been studied. When Solow (1957) studied economic growth in the United States, he found that most of the growth could not be explained by the two traditional factors of production (capital and labor), and he attributed the "unexplained" growth to the residual to technical progress. Later investigations by Dale Jorgenson, Zwi Griliches, and others reduced the residual considerably (e.g., by using better measurements of capital and by incorporating human capital), but it still remains quite high. This means that economists basically cannot account for all the productivity growth Western economies experienced during the past 100 years. To solve this problem, endogenous growth theory developed during the 1980s and the beginning of 1990s. The main idea is to incorporate the externalities that research and development activities generate because the benefits from these cannot be captured completely by the companies that carry out these activities. These externalities will therefore contribute to growth without being accounted for in the usual way that we analyze productivity growth. However, there are other externalities that also should be accounted for, such as networking externalities or social capital (Dasgupta, 1999). In this context, there is one particular externality that is of interest — environmental or resource externality. Because environmental resources or natural resources in general often lack well-defined property rights, they are not transacted on markets and therefore not accounted for in the standard national accounts (SNAs.) This omission of natural capital in growth accounting studies may explain at least part of the residual.

II. NET NATIONAL PRODUCT

Aggregate measures such as GNP or GDP were not constructed to measure welfare or well-being. They were aimed at measuring total monetary income in an economy and the total supply of goods produced in man-made facilities to provide economic planners with a database suitable for economic policies. However, despite warnings from many economists, GNP and GDP became used as indices of welfare. During approximately the past 25 years, economists have tried to define welfare and construct indices measuring welfare, and there is now a substantial literature on the subject. Instead of reviewing the literature, I will discuss some issues not very much discussed. Furthermore, most of the literature is based on the assumption that the economy is following an optimal growth path, which is rarely a realistic assumption. Instead, we will assume that we are able to make forecasts arbitrarily into the future.¹

The issues that will be discussed in this section are

- The notion of social well-being
- Social well-being and population growth
- The search for a linear index—net national product (NNP) as a marginal social cost–benefit criterion for elementary projects
- The search for a linear index—NNP as a measure of sustainable development
- Sustainable development and technical progress

A. Social Well-Being

In order to discuss social well-being, it is useful to imagine a social planner who is in charge of planning an economy from now (date 0) to infinity. Koopmans has convincingly shown (1960, 1972a, b) that the rational social planner should evaluate different policies with regard to how they affect the present value of the stream of future utilities, where the utility function is strictly concave and is a function of all the factors that influence the current well-being. In other words, the social welfare function is written

\[ W = \int_0^\infty e^{-\delta \tau} u(c(\tau)) d\tau \]  

(1)

where \( c(\tau) \) is the rate of consumption at moment \( \tau \). In principle, \( c(\tau) \) is a vector, the components of which represent all the factors that affect well-being at time \( \tau \). However, it will not change any conclusions if we restrict ourselves to the interpretation that \( c \) is the aggregate consumption good.

One of Koopmans’ condition is that \( \delta > 0 \); that is, the discount rate must be strictly positive. The discount rate is necessary in order to be able to define a social well ordering over all possible future paths of utilities. However, this is the rate for discounting utilities. The

¹ The basic reason behind the assumption of an optimal growth path in much of the literature is that predictions become very simple. It will be shown that nothing essential will change when we switch to arbitrary allocation mechanisms.

Jorgenson (1995a, b) provides masterful surveys of these issues.
rate for discounting consumption will in general be different and depends on the growth rate of consumption. The formula is

$$r = \delta + \eta g$$

(2)

where \(r\) is the consumption discount rate, \(\delta\) is the utility discount rate, \(\eta\) is the elasticity of marginal utility of consumption, and \(g\) is the growth rate of consumption. It is clear that if \(\delta\) is small and the growth rate is sufficiently negative, the social planner will want to discount future costs and benefits measured with consumption as a numeraire (i.e., the way we usually measure them in cost–benefit analysis) with a negative interest rate.

The strict concavity of the utility function guarantees an attitude in favor of equalization between generations. Holding everything else unchanged, a transfer from a rich generation to a poor generation will increase social welfare.

1. Mathematical Preludes

No in-depth mathematics will be used in this section and an elementary knowledge of calculus should be enough for the derivations made here. However, reading this section is not necessary for an understanding of later sections.

At time \(t\), the economy has inherited assets from the past. Denote the vector of these assets \(\mathbf{K}_t\). Assume that the social planner can predict the future flow of consumption, given \(\mathbf{K}_t\). In order to do this, the social planner must know how these assets are going to be used (now and in the future) for consumption and for accumulation of some of the assets and perhaps depletion of others (in particular, stocks of nonrenewable resources). Such predictions can be summarized by an allocation mechanism, which will be called \(\alpha\):

$$c(\tau) = \alpha(\tau, t, \mathbf{K}_t), \forall \tau > t$$

(3)

Thus, the mapping \(\alpha\) is the information the social planner uses for mapping forecasts.

Note that \(\alpha\) is a function of the initial stocks but also of calendar time \(t\). The reason for this is that there may be autonomous changing over time. If there is exogenously technical progress, for example, future predicted consumption will of course depend on this and \(\alpha\) must therefore depend on calendar time. Other reasons for autonomous changes in the allocation mechanism may be trends in trade and forecasted changes in government policies. I will discuss these issues later.

Given the allocation mechanism, the social welfare beginning at time \(t\) will be a function of the capital stocks at \(t\), the allocation mechanism, and the calendar time. Thus,

$$W = V(t, \alpha, \mathbf{K}_t)$$

(4)

\(V\) gives the social welfare achievable from the initial stocks \(\mathbf{K}_t\) with the allocation mechanism \(\alpha\).

A marginal change in one of the stocks at time \(t\) will change the welfare, and this change is basically the marginal value of that stock; that is,

$$p_i(t) = \frac{\partial V(t, \alpha, \mathbf{K}_t)}{\partial K_i}$$

(5)

where \(K_i\) is the stock of asset \(i\) at time \(t\). In most of the literature on green accounting, the accounting prices are those that support an optimal growth path. The prices defined here do not. However, they reflect the true values of the initial stocks at time \(t\).

It is practical to define the Hamiltonian \(H\) at time \(t\) as

$$H_t = u(c(t)) + \sum_{i=1}^{N} p_i \frac{dK_i}{dt}$$

(6)

One can now show that

$$\frac{dp_i}{dt} = \delta p_i - \frac{\partial H_t}{\partial K_i}, \quad i = 1, 2, \ldots, N$$

(7)

Although these equations are formally identical to the equations governing the costate variables in Pontryagin's maximum principle, they do not reflect any optimization except that the prices are the true measures of the marginal social values of the initial stocks.

B. Population and Welfare

So far, I have neglected population changes in the discussion of social welfare. However, we know that humans have a finite life and new generations will be born. How do we take this into account when we try to formulate a welfare function for a society?

The simplest way is perhaps to assume that population changes exogenously in a predictable manner. Then, at each moment in time we can represent the welfare of the cohort by the utility of an individual with average per capita consumption multiplied by the number of individuals. However, this is seriously flawed

* See Mäler (1999) for a proof.
in that fertility behavior is not exogenous. We now know that human reproduction behavior is governed by many social and economic factors. There are many studies showing that reproduction depends on the need for support during retirement, on the need for labor, on the need for risk diversification, and of course because children can be regarded as consumption goods—that is, they give immediate welfare to the parents. Dasgupta (1993, 1997) provides discussions of these issues and references to empirical material. Thus, we should treat fertility as endogenous, something that depends on the economic system in all its characteristics. However, this is exactly what the allocation mechanism introduced in the previous section represents. Thus, the population at any particular future point of time is determined by $\alpha$.

It is now easy to assume that the welfare function can be written

$$
\int_0^\alpha e^{-\beta L(\alpha(0), K_0)} u(c(t)) \, dt
$$

(8)

However, this formulation does not take into account the fundamental difference between a potential human being and an actual human. What is the value of having one more individual to that individual? There is no reasonable answer to this question [see Dasgupta (1997) for an extremely interesting discussion of these issues]. So far, we do not have an ethical base for assessing welfare to endogenous population changes.

C. A Marginal Cost–Benefit Rule

Define NNP with utility as the numeraire as the linearized Hamiltonian

$$
\text{NNP} = u'(c) c + \sum_{i=1}^n p_i \frac{dK_i}{dt}
$$

(9)

If, instead, we choose consumption at time 0 as the numeraire, NNP is defined by

$$
\text{NNP} = c + \sum_{i=1}^n \tilde{p}_i \frac{dK_i}{dt}
$$

(10)

where $\tilde{p}_i = p_i / u' (c(0))$.

Note that NNP or å is a linear index in all quantities, which makes it an interesting measure. A non-linear measure such as the Hamiltonian is hopeless in terms of empirical applications. We cannot estimate all the consumers' surpluses needed to get an empirical estimate of the Hamiltonian.

Second, note that $\epsilon$ is basically a proxy for all variables that affect current utility. Therefore, all these variables must be included in a generalized consumption set. Among these variables is the disutility of labor, which leads us to the conclusion that the wage bill, as long as the wage rate reflects the disutility of work, should be deducted. Immediate environmental damages should also be deducted. In all these cases the damages should be valued at a rate that reflects the marginal disutility of the environmental damage with consumption as the numeraire.

Third, note that the investment part of the NNP must include net changes in all assets that will affect future well-being. This means of course that the current narrow asset boundary in SINs must be substantially extended.

Also note that the asset prices $p_i$ must correctly reflect social the scarcity values captured by Eq. (7). These prices will not always coincide with market prices. However, surprisingly often, market prices will capture the social scarcity values of assets that are transacted on markets. However, for all the ecological assets, the values must be estimated by modeling the ecological systems and their connectedness. There is a growing literature on these procedures.

It should be noted that the NNP measure so defined deviates radically from the United Nations recommendations. The NNP measure we have defined has one important property, namely, that if there is a small perturbation (so that price changes are small) of the allocation mechanism during a small time interval, and if this small perturbation increases the social well-being, then it will also increase NNP and vice versa. This is what makes NNP interesting—a linear marginal cost—benefit criterion with which we can evaluate such perturbations (which henceforth will be called policy reforms).

Here, we consider discreet time, and the following example will indicate the use of the theorem stated previously. Assume that there is one allocation mechanism $\alpha$ and we consider a perturbation or policy reform $\Delta \alpha$ that for the first period presupposes the same allocation as $\alpha$ did for the second period. We compute the change in NNP when we make this policy reform and this change is positive. This can be interpreted as saying that the second period gives higher social welfare than the first period. By following the allocation mechanism.
$\alpha$, welfare increases over time. However, note that this depends on the assumption that the prices do not change much.

This theorem can now easily be generalized to situations in which we take atemporal equity into account, and even population changes can be accommodated. The trick is to find the appropriate shadow prices.

D. The Hamiltonian as Constant-Equivalent Utility

In the previous two sections it was shown that NNP can be used as an index for conducting social cost-benefit analysis of policy reforms. However, the theoretical literature on green NNP has been directed toward a quite different end (Weitzman, 1998). It has argued that NNP measures "constant-equivalent consumption."

It can be shown that the present value of a constant stream of utility equal to the Hamiltonian at time zero is the maximum feasible constant utility stream that an economy can afford. This was first shown by Weitzman in the case in which the utility function is linear. In this case, NNP and the Hamiltonian coincide, and NNP gives the maximum constant equivalent consumption.

However, a linear utility function is ethically flawed: It is insensitive to distributional issues. Furthermore, a large body of evidence concerning household saving behavior is at odds with linear utility functions.

E. Social Well-Being and the Concept of Sustainability

The World Commission (1987) defined "sustainable development" as an economic program in which, loosely speaking, the well-being of future generations is not jeopardized. There are many possible interpretations of this. Consider the following:

a. An economic development is sustainable if $dU/dt > 0$, where $U_0 = \lim U$, as $t \to -\infty$.

b. An economic development is sustainable if $dV/dt > 0$.

c. An economic development is sustainable if $dV/dt > 0$, where

\[ V_t = \int_0^\infty e^{\alpha U(C_t)} \, dt \]

It is clear that a lacks ethical foundation. For example, it may be desirable to reduce $U$ in the short run in order to accumulate assets so that the flow of $U$ is still higher in the future. In this sense, b offers greater flexibility in ethical reasoning: It permits initial sacrifices in the current standard of living, $U$ (a burden assumed by the generation engaged in the reasoning), but requires that no future generation should have to experience a decline in its standard of living.

In contrast to c, the focus of b. as a notion of sustainable development is social well-being, $V$. The criterion permits the first generation to make initial sacrifices in $V$ (relative to the past) but requires that social well-being should never decline in the future. Note that although b implies c, c does not imply b. In other words, c. is more general. In what follows, we adopt c. as our notion of sustainable development and develop criteria for judging whether a given economic program represents sustainable development.

One can now easily show that

\[ \frac{dV}{dt} = \frac{dV}{dt} + \sum p_i \frac{dK_i}{dt} \]

The first term on the right-hand side is the autonomous change in $V$, reflecting exogenous technical progress or exogenous changes in terms of trade. We will discuss this term in the last section. For now, we assume that there are no autonomous changes. The previous equation simply indicates that the rate of change in welfare is equal to the value of the net investment in the economy. Thus, an economic program represents sustainable development if, and only if, the program net investment in the economy's capital assets is always nonnegative.

The result has intuitive appeal. It says that social welfare is higher today than it was yesterday if the economy is wealthier today. Here, an economy's "wealth" is interpreted as the accounting value of all its capital assets, and wealth comparisons are made at constant prices. In a famous article, Samuelson (1961) argued in connection with national income accounting that welfare comparisons should deal with "wealth-like" entities. Proposition 4 formalizes this insight.

Note, however, that what we have obtained is an equivalence result: The theorem cannot on its own tell us if sustainable development is feasible. Whether the economy is capable of growing wealthier indefinitely depends on, among other things, the extent to which different assets are substitutable in production.

This idea of examining changes in wealth dates back to Samuelson (1961). The connection to sustainable development was first suggested by Pearce and Atkin-
son (1993), although they did not derive the theorem rigorously and they did not interpret it as an equivalence result. The idea was then investigated by the World Bank, which published many attempts to measure the value of net investment or genuine savings [see Expanding the Measure of Wealth (1997) and Kunte and Clemens (1998) for further details.]

Note that we cannot in general use NNP to determine whether the economy is on a sustainable path. Only if the prices are stationary is an increasing NNP equivalent to saying that the economy is on a sustainable path.

In conclusion, NNP can be used for cost benefit analysis in situations in which prices do not change very much. In particular, in such a situation it may give some guidance as to whether social welfare is increasing or not. Note that there is no conflict between growth in the NNP and the concern for the environment. These concerns have been incorporated into the linear index. If the economy is on a path in which environment is degraded, this will be captured by the NNP, and it can be expected that NNP will decrease if the degradation is sufficiently large.

NNP is not useful for determining whether the economy is on a sustainable path because the relative prices will change along the path. Here, concepts related to wealth become more interesting. In particular, the value of the net investments in a time period gives a correct criterion for judging whether the economy is on a sustainable path. However, it is only a necessary condition. The sufficient criterion is that in each future period, the value of net investments must be positive. A priori, we do not know whether this is feasible.

III. ENVIRONMENTAL KUZNETS CURVES

Since the early 1990s, economists and econometricians have been industrious in estimating empirical relations between GDP and environmental quality indicators. Typically, they have used cross-sectional data—country data for a particular year. For some quality indicators, they have found a relation that looks like an inverse U (Fig. 1).

The interpretation is simple. Very poor countries with low industrialization are not damaging the environment much and as a result the environmental quality indicator is good (in this case, a low sulfur emission). When the country starts the growth process, the environmental damages will increase. When income per capita increases, the demand for a cleaner environment will increase, environmental legislation will be enacted, and the environment will improve. Because the curve is similar (but inverse) to the curves Kuznets (Economic Growth and Income Inequality, 1955) estimated for the relationship between income inequality and GDP per capita, they have been known as the environmental Kuznets curves. For an overview and examples of environmental Kuznets curves, see Environment and Development, 2 (4), October 1997.

The breakthrough for this kind of analysis came with the World Development Report (1992), which was devoted to the environment. The existence of these curves was taken to be an indication of possible win-win situations. By stimulating growth, one would also in the long run stimulate environmental regulations. It is clear, however, that the analysis is quite muddy complex.

First, environmental Kuznets curves have only been established for a few environmental indicators. Second, at least earlier, the specifications of the relation between the quality measure and GDP per capita were quadratics, which almost certainly forced the curves to look like an inverse U. Third, the studies did not include environmental spillovers between countries. Fourth, they did not examine possible relations between indices of freedom and the environment. It has been shown that whenever people have had the right to voice concern about environmental degradation, the environment has improved, irrespective of the per capita income. Locally, in many cultures people have had a direct influence on, for example, local water pollution, which has improved even in very poor countries. It is therefore possible that the environmental Kuznets curves measure not the effect of income growth but growth in freedom.

However, most important is that the environmental Kuznets curves—if they exist in any meaningful way—
are not optimal in any sense of the concept. Typically, a country would do much better to develop institutional and regulatory reforms for better environmental management than just trust that economic growth will automatically solve environmental problems. In this sense, the belief in environmental Kuznets curves and the associated belief in win–win situations are very dangerous.

IV. TECHNOLOGICAL CHANGE AND GROWTH ACCOUNTING

Productivity growth as discussed previously is productivity growth in GDP in which the flow of services that are not transacted on markets are excluded (with of course some important exceptions, e.g., government output). Here, we are interested in productivity growth in NNP as defined previously. There is no reason why productivity growth in GDP would correspond to a similar growth of NNP. Furthermore, if, as Dale Jorgensen (1995a, Chap. 1) pointed out, changes in energy prices affected the observed productivity growth rate substantially, it should be clear that the utilization of other natural resources should also affect the growth rate of the total production. Thus, we should analyze the following issues:

• Growth in NNP
• The role of natural capital in the growth of NNP

The following calculations are very speculative, but I hope that some day someone will find it worthwhile to study the empirical consequences from the analysis. I use the simplest possible model to demonstrate the main ideas (which probably will be seen to be perhaps too obvious).

Let there be one aggregate good \( x \) which is produced with man-made capital \( K_e \) and one input representing natural capital services, denoted \( y \). Thus,

\[
x = f(K_e, y)
\]

Assume that the production function \( f \) is homogeneous to degree 1.

The total output is used for consumption \( c \), for investment in man-made capital \( I = K_e \), and for investment in man-made capital for exploiting the natural resources \( t = K_n \). Let the production function for \( y \) be

\[
y = g(K_n)
\]

Thus, \( y \) is an intermediary good in the system and \( x \) will correspond to GDP:

\[
x = c + K_e + K_n = c + K
\]

Assume that capital is freely mobile between the two uses so that we can reasonably talk about the total capital stock \( K = K_e + K_n \). Then we can define the productivity growth in GDP as

\[
\theta = \frac{1}{x} \frac{dx}{dt} - \frac{1}{K} \frac{dK}{dt}
\]

Now, let the dynamics of the natural or ecological capital \( K_e \) be

\[
\frac{dK_e}{dt} = \phi(K_e) - y
\]

Assume that there is an institutional failure in the economy so that there are no assigned property rights to natural capital and therefore no market transactions in \( K_e \). This is of course the reason why investments in natural capital are not included in GDP.

NNP according to the definition in equation is

\[
NNP = c + \frac{dK_e}{dt} + \frac{dK_n}{dt} = x + \frac{dK_e}{dt}
\]

It is clear from Eq. (16) that a positive productivity growth for GDP can be offset by depreciation of the stock of natural capital so that the productivity growth of NNP is zero or even negative. In fact, if we assume that \( K = 0 \), we have

\[
\frac{1}{NNP} \frac{dNNP}{dt} - \frac{1}{K_e} \frac{dK_e}{dt} = GDP \theta + \frac{K_n}{K_e} \left\{ \frac{p_t K_n}{K_e} \frac{K_n}{K_e} - 1 \right\}
\]

(17)

The last bracket in Eq. (17) will surely be negative because of the overexploitation of the resource as a result of the institutional failure. Thus, this bracket will compensate for the positive productivity growth of GDP.

In this case, because we know that the production func-
tions are stationary, we know for sure that the productivity growth rate of NNP (if the production functions have constant returns to scale in $K$, $L$, and $E$) must be zero. We can therefore conclude that even if measured GDP growth rates show a positive productivity growth, this does not necessarily imply that NNP will show growth irrespective of factor inputs.

This result also follows from the observation that conventional SNA regards the inputs of resources as intermediary goods (if there are costs in producing them and it neglects them completely if they are supplied free of any costs to the production processes), and the estimation of an aggregate production function with only labor and capital as inputs, necessarily will be biased because resources are the basis for material production. Thus, the total factor productivity of GDP should be measured as

$$\frac{1}{x} \frac{dx}{dt} = w_K \frac{1}{K} \frac{dK}{dt} + w_L \frac{1}{L} \frac{dL}{dt}$$

(18)

where $w_K$ is the value share of man-made capital and $w_L$ is the value share of the resource input. This will necessarily be zero if the production function is linearly homogeneous and stationary. Thus, it may be that the neglect of resource inputs in the production functions is an important explanatory variable of the measured positive factor productivity growth. However, the only way to find out whether this is important is to carry out new empirical measurements. In conclusion, it does not seem reasonable to assume autonomous productivity growth in models designed to create a new accounting system for welfare measurements. Therefore, the argument for a nonstationary value function is not necessarily true.

ECONOMIC VALUE OF BIODIVERSITY, MEASUREMENTS OF

Robert Mendelsohn
Yale University

I. Introduction
II. Value to the Economy
III. Quality-of-Life

GLOSSARY

biodiversity Number of species on the planet.
local diversity Number of species or ecosystems in a small geographic area.
market value Benefit of wildlife or species as an input into the economy.
quality-of-life value Benefit of wildlife or species to people’s well-being or happiness.
williness-to-pay Expression by people of strength of preference in dollar terms.

BIODIVERSITY IS USED IN MANY DIFFERENT WAYS including the number of species on the planet, the number of species in one place, the number of individuals of desired species, the genetic diversity of a given species, and the ecological diversity of ecosystems. Each of these meanings implies a set of different values. This article reviews how we measure these different values and provides an overview of the values that have been measured to date. There are two broad types of biodiversity values. Market values reflect how biodiversity serves as an input to economic activities such as agriculture, construction, and medicine. Quality-of-life values reflect ways that biodiversity makes our lives richer simply by increasing our appreciation of life itself.

1. INTRODUCTION

Before one can describe the values that society places on biodiversity, it is first necessary to define what biodiversity means to people. Unfortunately, the term has come to mean many different things, which only complicates valuation. A narrow definition is that biodiversity represents the number of species on the planet. Hence the loss of a species diminishes biodiversity. This definition clearly links biodiversity with endangered species. Biodiversity has also been used to compare one place to another. Local diversity measures this type of biodiversity: places with more biodiversity have more species per hectare. This definition recognizes the value of complex ecosystems, as well as the value of a variety of ecosystems across a landscape. A third definition of biodiversity reflects the value of all living things: a place with more songbirds, more deer, more butterflies, and more trees is a “better” place. In this case, biodiversity is a pseudonym for the overall population. The term biodiversity means all of these things to society, making a precise measurement of the value of biodiversity difficult.

There is no single value of biodiversity since there is no single definition of what the word actually means. Biodiversity values are really only clear as one moves
from the general term to specific questions. Rather than
determining a single value of biodiversity, the literature
on valuation has attempted to measure how important
specific aspects of nature are to people. For example,
what would people pay to prevent a specific species
from going extinct? What would people sacrifice to
keep more complex ecosystems such as mixed-species
forests in place? How much income would people give
up to have a variety of ecosystems across the landscape
rather than having only one or two? What would people
pay to increase the population of particular creatures
in their local woods?

Biodiversity values have often been further divided
into two types: market and quality-of-life values. The
market values reflect the interaction between nature
and the economy, whereas the quality-of-life values
involve interactions directly between nature and people.
Methods to measure market values are well developed
and we consequently know more about market values.
Quality-of-life values are more difficult to measure.
There are many of such values we have just begun to
understand, much less measure. Although these quality-
of-life benefits are technically difficult to measure,
they cannot be dismissed because they are likely to
be the primary motivation for protecting species and
wildlife populations.

The remainder of this article is divided into a review
of biodiversity values for market and quality-of-life ser-
tices. In each case, we begin discussing the methods
and then review existing measurements. For both mar-
ket and quality-of-life, we examine species diversity,
local diversity, and natural populations. The article con-
cludes with an overview of what has and has not been
measured, discusses research priorities, and briefly
hints at policy implications.

II. VALUE TO THE ECONOMY

Biodiversity is one of many inputs into the economy.
From medicine to timber, biodiversity provides raw
materials for many economic processes. Although these
inputs are not always traded in markets, they nonethe-
less fuel market activities. By valuing the resulting mar-
ket activities, one can deduce the value that each input
contributed. Of course, one must be careful to value
all inputs to each economic process. One cannot assign
the market value of outputs to just one of the many
inputs required to make a good. For example, plant
biodiversity may be an input to pharmaceutical research
but it is only one of many inputs, including laboratories,
technicians, and clinical research. In this section, each
of the multiple definitions of biodiversity is examined to
determine what value they contribute to the economy.

A. Diversity

The diversity of species on the earth is of economic
value because the diversity offers many alternative ser-
tives. For example, the diversity of plants has been
used to find cures for diseases. Plants, in their constant
struggle for survival, have developed numerous de-
fenses to limit consumption by predators. Some of these
chemicals have important medical qualities. Many ex-
isting pharmaceuticals have come from plants. Some
47 drugs have come from tropical forest plants alone
(Soejarto and Farnsworth, 1989). Given that there are
250,000 plant species in the world, there is a strong
possibility that additional undiscovered drugs lie hid-
den in this diversity. Assuming that one out of a million
samples contains a hidden drug, there may be as many
as 325 useful drugs still hidden in tropical plants alone
(Balick and Mendelsohn, 1995).

What is the value of these hidden drugs? The drugs
themselves are worth billions of dollars. A successful
drug is worth about $94 million to a drug company
(OTA, 1993). Such a drug is worth about $450 million
to society when one includes the resulting health ben-
fits, taxes, and revenues beyond the patent period (Bal-
ick and Mendelsohn, 1995). Multiplying both figures
by the number of hidden drugs suggests that private
companies would pay $30 billion and society would
pay $145 billion for these drugs. This is the value of
the drugs, but not the value of the biological component
since many other inputs went into creating each drug.
For example, finding the samples, identifying active
chemicals, and developing a drug that can be marketed
costs over $100 million per drug. Pharmaceutical com-
panies should not be willing to pay much for samples
at all since the cost of developing new drugs from these
samples is likely to be greater than the expected reve-
uues. In contrast, society would still find the drugs
valuable since society obtains more benefits from the
drugs than companies can get. Society would be willing
to pay about $40 billion for these samples. When spread
over 125,000 plants, this amounts to about $320,000
per plant. Allocating this value to each of the 3 million
hectares of tropical forests suggests that each hectare
is worth an average of about $13. Of course, once the
plants on a particular hectare are investigated, they will
no longer have any more value in this regard. This
raises serious questions about how to collect these reve-
uues since many landowners will compete to be the
one and only collector of each plant.
Diversity may also be of value to crops and trees because it yields a broad gene pool. Although this gene pool may not be needed today, it could serve as a resource against future pathogens and problems. Because farmers and foresters rely on improved varieties, many scientists are concerned that the crop gene pool has become too narrow. Despite the success of modern farms and forests, these scientists argue that farmers need more diversity and thus it is imperative that we protect plants in the wild that are related to modern crops. Similar concerns are raised to protect old varieties that have fallen out of favor. It is possible that noncommercial plants related to valuable crops could be valuable in the future in order to create a broader gene pool to be used against future pathogens. However, it is hard to quantify the market value of this potential since most modern crop varieties appear to be doing well in relying on a more select gene pool that is already well protected. It would be useful to quantify the additional value of sustaining marginal crop varieties against some future date when they might be needed. The known cost of sustaining varieties that have little value today would have to be weighed against the uncertain benefit in the future when they might be needed.

### B. Local Diversity

Local diversity has often been championed as a defense against the ravages of nature. Whether one is considering hurricanes, ice storms, and other severe weather or whether one is concerned about insects, rust, or viral attack, ecologists argue that more diverse systems are more robust. For example, by planting a diversity of crops, a farmer can protect his or her income from weather, insects, and pathogens. Even if some crops are destroyed, the other crops will likely survive, thus assuring at least some income. Modern farms tend to plant a wide set of crops to protect against uncertainty from varying market prices as well as the adversities facing all farmers. Similar schemes can protect forests as well. By growing trees from a wide range of species and in a number of age groups, foresters can reduce the likelihood of catastrophic events.

Some efforts to combine forests and farms have also been practicing local diversity. Windbreaks across flat areas have been used as a way to protect crops from high winds. Mixed agroforestry methods have been used in the tropics to provide a portfolio of outputs (Padoch et al., 1985) as well as to sustain soils (Montagnini and Mendelsohn, 1997). These land use planning practices have been successful in reducing some of the damages that are more easily afflicted to a homogeneous landscape.

### C. Population

Sometimes plants and animals are a direct input to the economy. In this case, biodiversity represents the size of relevant populations. The most significant biological population to humans lies in the agricultural sector. Approximately 1.9 billion tons of grain, 0.6 billion tons of tubers, and 1.5 billion tons of sugar crops are grown each year. In addition, approximately 181 million tons of meat are harvested annually. Agriculture accounts for approximately 6% of the world’s gross domestic product, or about $1.2 trillion overall. This number reflects the marginal value of food. Of course, people would pay a lot more for food rather than be without it entirely. Assuming that people would pay twice as much for food if only half of the food was available, the all-or-nothing value of food would be $2.4 trillion.

Another economic sector that depends on raw materials from nature is forestry. The timber industry harvests trees from more or less natural settings and converts them into lumber and paper products. For the last 200 years, the industry has relied heavily on cutting natural stands of trees. Originally, this was done unsustainably as the industry harvested the vast stands of old growth around the world. As these stands have become rare, much of the industry has shifted to growing trees on plantations. The worldwide industry is approaching sustainability as regeneration now almost balances harvest rates. Once this balance is reached and maintained, trees can be harvested indefinitely from a given land base. The timber industry currently harvests 1600 million cubic meters every year (IPCC, 1996). Over half comes from temperate forests (890 million m³), another fourth from boreal forests (430 million m³), and the remainder from tropical forests (280 million m³). In contrast, most of the world’s land in forest is currently tropical (27.6 million km²) and boreal (13.8 million km²), with only 5.4 million km² in the temperate region (IPCC, 1996). The timber industry is most dependent on the productive lands in the temperate and subtropical parts of the globe.

This industry produces an annual output worth $418 billion (IPCC, 1996). However, a large fraction of this estimate is value added from production. The value of the trees themselves is more difficult to estimate. Assuming that the value of harvesting an additional tree, the stumpage value, is about $20/m³, the annual market value of the 1600 million m³ would be about $32 billion per year. This is the marginal value of the harvest.
The most abundant physical product from the forest is not industrial wood but rather fuelwood and charcoal. Each year approximately 1750 million m$^3$ of wood is used for energy. The vast majority of this use occurs in tropical regions, which rely on 1370 m$^3$ for energy. Temperate forests produce 20% of the wood energy (370 million m$^3$) and boreal forests produce very little (10 million m$^3$) (IPCC, 1996). Although the use of wood for energy consumes more forest biomass than any other use, it is not the most valuable activity. Wood is often used by communities that cannot afford more expensive sources of energy (such as fossil fuels). The average price of a cubic meter of wood for biomass is probably in the neighborhood of about $5/m^3$. The global market value of fuelwood is around $9 billion annually.

In addition to these foregoing products from trees, there is a host of non-timber forest products (NTFPs) that people enjoy around the world. The more diverse the forest, the more NTFPs that are present. Yet even in relatively simple northern forests, people enjoy wild rice, berries, mushrooms, boughs, maple sugar, and food resins. In the tropical zone, forests produce natural medicines, fodder, fruits, latex, rattan, roofing material, dyes, and other wood resins. It is difficult to quantify the global value of these products since most are traded only locally and so escape official enumeration. However, local studies of selected tropical forests suggest that these NTFPs are often as valuable as timber (Peters et al., 1989; Balick and Mendelsohn, 1992; Grimes et al., 1994; Houghton and Mendelsohn, 1996; Muntz-Miret et al., 1996). As a rough approximation, it is likely that the value of NTFPs is equal to the value of timber from tropical forests, or about $6 billion each year.

III. QUALITY-OF-LIFE

Although biodiversity makes a large contribution to the world’s economy, it is likely that the most important services that humans receive from nature are to our quality-of-life. Many aspects of biodiversity are not used by the economy and so provide no market value. Nonetheless, if we were to lose these species and populations, people would suffer a great loss. People clearly enjoy nature and obtain a great deal of pleasure from it.

A. Diversity

The earth contains an amazing diversity of plants and animals. Approximately 1.5 million living species have been identified. Almost 1.25 million of these species are arthropods, or insects. Scientists estimate that there are as many as 250,000 flowering plants, 80,000 fungi, and 100,000 mollusks. Only 30,000 species are vertebrates. Although there have been some major mass extinctions in the geological record, the number of higher-order species that have perished in industrialized nations is few. In fact, the vast preponderance of species lost today are the assumed losses of insects from the clearing of tropical forests. Scientists predict that each of these hectares likely contains a certain number of unique insects that are lost when the trees are removed. This is a predicted loss, since no one has actually identified the insects in these forests that have now disappeared.

Surveys of public opinion clearly indicate widespread and strong interest for species protection. Despite frequent attacks from land developers, business groups, and some industries, public support for endangered species and other wildlife continues to be strong. However, public preferences for which species deserve protection are complex. For U.S. society is not equally concerned with all species. People express the strongest preference for flagship or charismatic species (Kellert, 1984). These include North American animals such as the grizzly bear, black-footed ferret, Florida panther, and bald eagle. International examples include lions, elephants, tigers, rhinoceroses, seals, monkeys, and apes. In general, people appear to be willing to pay the most for these charismatic animals. For example, using a survey on the willingness to pay, Brookshire et al. (1983) found that people would pay between $10 and $26 to protect grizzly bears and Boyle and Bishop (1986) found that eagles were worth between $10 and $31 per person. Despite the broad enthusiasm for species protection, it is not clear that people are willing to sacrifice very much to protect lower-order animals and plants. For example, Boyle and Bishop (1986) found that people were only willing to pay between $4 and $5 to protect the striped shiner, a small fish. Valuation studies have not specifically determined a value for a broad class of lower-order animals. It is most likely the case that people would pay for their protection as part of a larger plan to protect entire ecosystems. However, the valuation of entire ecosystems has not yet been done.

B. Local Diversity

Scientists have determined that certain ecosystems have more species per hectare than others. For example, species diversity generally rises as one approaches the
equator from either pole. The highest number of endemic species per hectare tends to be in tropical locations. It is possible that people have preferences concerning whether they would like to have more species in the ecosystems that they live in. Unfortunately this has not been tested, so it is difficult to know. It is clear that certain “hot spot” locations with high numbers of endemic species have become desirable travel destinations. Madagascar, the Philippines, and the Galapagos Islands are all sites where ecotourists flock to see the high numbers of endemic species.

Local diversity can also mean that there are many ecosystems within a small region. Sometimes terrain can create small microsites with unique climates. For example, mountainous regions near the coast can have a wide variety of ecosystems in a relatively small area. This diversity gives people many landscapes to enjoy locally. Although most of this diversity is a natural phenomenon, it can be affected by land use patterns. For example, if people drain wetlands, the only land remaining may be an upland ecosystem. By draining the wetlands, people have simplified the landscape. The many recent laws to protect wetlands and other ecosystems suggest that this diversity has considerable value to people. Curiously, little valuation research has been done on the value of heterogeneous landscapes.

C. Populations

There is no question that people value local wildlife populations. A survey conducted by the U.S. Fish and Wildlife Service (1991) found that approximately one-half of Americans participated in some wildlife-related recreation. Of these, 76 million people enjoyed nonconsumptive activities such as bird watching, 35 million people fished, and 14 million hunted. Throughout America, people appear to derive great pleasure from having wildlife around them. Even with such common creatures as squirrels, sparrows, and pigeons, people are entertained by chance encounters with animals.

Economists have assigned values to wildlife interactions by using survey methods. For example, the techniques used to study endangered species protection (Brookshire et al., 1983; Boyle and Bishop, 1986) have also been applied to places and activities such as the Maine woods, duck hunting, and goose hunting.

Economists also measure values by observing the travel preferences of people. Because many people interact with wildlife by taking trips to outdoor sites, their choice of sites reveals how much they want to see different things. For example, with the simple travel cost method, visitation rates are compared with distances. The farther someone is willing to travel to see a site, the more valuable the site is. The relationship between visitation rates and distance reveals how much people are willing to pay to see the site. By calculating the area under this visitation function minus actual travel costs, one can determine the value of the site for a person. The total value of the site would be the sum of the values for all the visitors (Clawson and Knetisch, 1966; Brown et al., 1983). This model has also been extended to examine a set of sites (Burt and Brewer, 1987; Cichetti et al., 1992).

A weakness of the simple travel cost method, however, is that it values sites only in their entirety. One of the questions facing land managers is the valuation of changing site characteristics. For example, a manager might consider harvesting some old growth at a site or increasing deer or elk populations. To place a value on site characteristics, one must examine the set of sites that people choose from. Two techniques have been developed to value site characteristics: discrete choice and hedonic travel cost. The discrete choice method looks at all the available sites and determines a quality index that can explain why people choose particular places more often (Morey, 1981). The hedonic travel cost method examines the attributes of the places people choose and tries to estimate the marginal cost or value that people assign to each attribute. The hedonic travel cost then goes further and tries to estimate a demand function for each attribute (Brown and Mendelsohn, 1984).

The literature on valuing site attributes indicates that natural site qualities are important to people. For example, steelhead trout anglers care a lot about the number of fish in a stream (Brown and Mendelsohn, 1984). In Washington state, they would pay an average of $5 per trip for just 1 more fish per day. Hunters care a lot about the number of deer per acre. Urban hunters would pay an extra $4 for one more deer per square mile in Pennsylvania (Mendelsohn, 1984). Hikers care about old-growth forests, clear-cuts, and the size of open areas in wilderness hikes in Washington (Englin and Mendelsohn, 1991). Their consumer surplus per trip is about $70 for old growth, $14 to avoid clear-cuts, and $67 for large rock and ice areas. This literature also revealed that what people would pay for certain characteristics declined as they experienced more of them. Although people would pay $88 to avoid a 20% reduction in the steelhead population at an average site, they would pay very little for more steelhead at a site where there is already a large population. The quality-of-life value of wildlife populations consequently appears to depend on their abundance.

GLOSSARY

**accounting price** In this context, a measure of the economic value of a resource in social terms, described as the increase in social well-being that would be enjoyed if one unit more of the resource were made available without cost, and expressed as the difference between the market price of the resource and the tax or subsidy that ought to be imposed on it.

**bifurcation point** A transitional boundary in the state of a dynamic system (such as an ecosystem), at which the stability or basic nature of the system changes due to alterations in its fundamental characteristics.

**intrinsic value** A measurement or description of the values inherent in a resource by virtue of its existence (e.g., a living organism), as opposed to its value for present or future use.

**option value** A variation on the concept of USE VALUE (see below); a measurement or description of the potential value of a resource for possible future use.

**net social benefit** A measure of the social benefit of a project, obtained by identifying the projects positives (favorable outputs) and its negatives (inputs, unfavorable outputs), then multiplying these by the accounting price of each commodity involved. The net result of comparing these positive and negative values will indicate the social benefit of the project.

**separatrix** Locus of points on the state space of a dynamical system separating different basins of attraction.

**shadow price** Another term for ACCOUNTING PRICE.

**substitution possibility** The possibility that the depletion of a given resource can be compensated for by one or more of various forms of substitution; e.g., by substituting a more plentiful natural resource for a scarce one, or by substituting a manufactured product for a natural one.

ANY ASSESSMENT OF THE VALUE of biodiversity should begin with an account of why we need to value it and the reasons market values would not be expected to suffice for the purpose. The first three sections discuss these matters in the wider context of valuing natural resources (biodiversity is but a special case). A transitional section (Section IV) shows how values can be translated into prescriptions for economic policy. Sections V–VII discuss the special problems that arise in valuing biodiversity and the techniques that are available for coping with these problems.
I. THE SUBJECT

Resource economists view the natural environment through the lens of population ecology. Since the latter’s focus is the dynamics of interacting populations, it has proven useful in resource economics to regard the functioning of the rest of the ecosystem as exogenously given. Well-known illustrations of this viewpoint include the use of the logistic function to chart the time path of the population of a single species of fish, the study of predator-prey interactions by means of variants of the Lotka-Volterra equations, and the estimation of growth in biomass of a species of trees at a given site. A prominent concern in resource economics has been to determine the rates at which a single resource would be harvested in different institutional settings. Thus, not only have socially optimum harvest rates been analyzed (Spence, 1974; Clark, 1976; Dasgupta and Heal, 1979; Hartwick, 1993) but also economists have determined harvest rates when harvesters have free access to the resource (Gordon, 1954; Dasgupta and Heal, 1979; Dasgupta, 1982). We now have an understanding of the effect on harvest rates of harvesting costs, the rates at which harvesters discount future costs and benefits, the productivity of the resource in situ, the “worth” of the harvest to harvesters, and the property rights regime in which the harvesting is done.

Environmental economists, in contrast, base their studies on ecosystem ecology. Here, the focus is on objects such as energy at different trophic levels and its rate of flow among them, the distribution and flows of biochemical substances in soils and bodies of water, and the flows of gases and particulates in the atmosphere. The motivation is to study the biotic and abiotic processes which underlie various ecosystem functions. Economic studies of global warming, eutrophication of lakes, the management of rangelands, purification of water in watersheds, and the pollution of estuaries are examples of such endeavor (Maler, 1974; Costanza, 1991; Nordhaus, 1994; Perrings and Walker, 1995; Chichilnisky and Heal, 1998). Such studies have provided valuable insights into the effects on ecosystems of the character of economic activities, as driven by technology, costs and revenues, discount rates, and the property rights regime that governs the ecosystem.

Formally, it is useful to interpret differences between resource and environmental economics in terms of the state variables that are taken to characterize complex systems (state variables are frequently called stock variables). In resource economics, state variables are “quantities” (biomass units for forests, cow dung, and crop residue; herd size, expressed in numbers, for animal populations; acre-feet for aquifers; and so on). In environmental economics state variables are frequently “quality” indices, such as those for air, soil, or water (although quality, for example, salinity, is typically inferred from quantity indices), with the intention to draw attention to ecosystem services. State variables are summary statistics, reflecting different forms of aggregation. Therein lie their virtue: They enable the analyst to study complex systems by means of a few strategically chosen variables.1

The viewpoint just discussed—that of distinguishing resource and environmental economics in terms of the state variables that summarize complex systems—has enabled economists to integrate problems of resource management with those of environmental pollution (Dasgupta, 1982). Insights from one field of study have been used for gaining an understanding of the others. The viewpoint also reminds us that environmental and resource economics is the study of renewable natural resource systems, when subject to human predation. Since it would be convenient to refer to environmental and resource economics by an overarching name, I do so in this article with the term ecological economics.2

The economics of biodiversity, still in its infancy (Perrings et al. (1994, 1995) are pioneering collections of studies on the subject), is all of the above, but it includes an additional complication in that it recognizes that aggregate statistics can mislead—for example, to devise schemes to manage a resource without understanding its function within the ecosystem of which it is a part can be a road to disaster because the ecosystem’s biodiversity can be a source of its productivity, including, for example, the system’s stability (Tilman and Downing, 1994; Tillman, 1997). In this article, I provide an account of valuation problems in ecological economics; they are, naturally, valuation problems as well in the economics of biodiversity. I then discuss some of the special problems that arise in the latter and techniques available for resolving them.

II. MARKET FAILURE

If you were to browse among such leading Western journals in ecological economics as the Journal of Envir-

---

1 This two-fold classification, based on the character of state variables, is implicit in contemporary ecology (Ehrlich et al., 1977; Roughgarden et al., 1989).

2 I am able to usurp the term from the literature because it appears to have no fixed meaning. "Ecological economics" seems to mean different things to different people.
ronmental Economics and Management, you would discover that a central concern in the field has been to devise ways by which it would be possible to ascertain the “value” of natural resources and the services they provide. A question that would inevitably occur to you is, why? Why should there be a special need to determine the worth of such resources? Why not rely on their market prices? More generally, we may ask why it would not do to rely on markets to guide decisions bearing on the natural resource base, be they global or local, in the way we do for so many other goods and services. In other words, we may ask why markets are not an adequate set of institutions for protecting the “environment.”

The answer is that for many natural resources, markets simply do not exist. In some cases they do not exist because the costs of negotiation and monitoring are too high. One class of examples is provided by economic activities which are affected by ecological interactions involving long geographical distances (e.g., the effects of uplands deforestation on downstream activities hundreds of miles away) and another by large temporal distances (e.g., the effect of carbon emission on climate in the distant future, in a world in which forward markets are nonexistent because future generations are not present today to negotiate with us). Then there are cases (e.g., the atmosphere, aquifers, and the open seas) in which the nature of the physical situation (viz., the migratory nature of the resource) makes private property rights impractical and therefore keeps markets from existing; in other cases, ill-specified or unprotected property rights prevent their existence or make markets function wrongly even when they do exist. In other words, environmental problems are often caused by market failure (but see Section III). Indeed, the phenomenon of externalities (i.e., exchanges among people which occur without their consent) looms large in what has traditionally been called environmental economics.3

Problems arising from an absence of forward markets for “transactions” between the present generation and those in the distant future are no doubt ameliorated by the fact that we care about our children’s well-being and know that they, in turn, will care for theirs in an intergenerational sequence. This means, by recursion, that even if we do not care directly about the well-being of our distant descendants, we do care about them indirectly. However, there is a distinct possibility that our implicit concern for the distant future via such recursion is inadequate due, for example, to institutional failure in other spheres of economic activity. This is why economists have argued that market rates of interest do not reflect socially desirable discount rates (Lind, 1982; Arrow et al., 1996; Portney and Weyant, 1999). In other words, market failure involves not only misallocation of resources in the present but also misallocation across time.

In each of these cases, the market prices of goods and services fail to reflect their social worth; typically, they are less than their social worth. In economics, the social worth of goods and services is called accounting price (or shadow price). The accounting price of a resource is the increase in social well-being which would be enjoyed if a unit more of the resource were made available costlessly. Therefore, a resource’s accounting price is the difference between its market price and the tax (or subsidy) that should be imposed on it. Needless to say, accounting prices reflect social objectives, ecological and technological constraints, and the extent to which resources are available.

It should be noted that externalities do not create market distortions; they are a form of market distortion. The presence of externalities leads to a wedge between market prices and accounting prices. Generally, laissez-faire economies are not much good at producing publicly observable signals of environmental scarcities. To illustrate, if there were free access to a resource base, the market price of the resource in situ would be zero. However, because it is in limited supply, its accounting price would be positive. Therefore, there is a directional bias in environmental externalities: Market failure typically results in an excessive use of the natural resource base, not an insufficient one.

One way to improve matters would be to impose regulations on resource users, for example, restrictions on effluent discharges, quotas on fish harvests, and bans on logging. Another would be to introduce a system of taxes, often called Pigovian taxes [in honor of Pigou (1920), who first discussed the difference between private and social costs in the context of environmental pollution]. Pollution charges, charges on the amount of fish harvested, and stumpage fees are examples. The idea underlying Pigovian taxes is to bring market prices (inclusive of taxes) in line with accounting prices. Each of the two schemes, quotas and taxes, has its advantages and disadvantages; some of the differences between the two become salient once we recognize not only that ecological processes are stochastic but also that resource users and government agencies do not

---

3 The early literature on ecological economics identified market failure as the underlying cause of environmental problems (Pigou, 1920; Lindahl, 1958; Arrow, 1971; Meade, 1973; Mäler, 1974; Baumol and Oates, 1975; Dasgupta and Heal, 1979).
have the same information about local ecology (e.g., the cost of waste disposal) (Meade, 1973; Weitzman, 1974; Baumol and Oates, 1975; Dasgupta, 1982). I will not discuss details here, but three points are worth noting. First, the two schemes are distributionally not equivalent: Under a quota, resource rents are captured by harvesters and polluters, whereas under a tax system they are collected by the tax authority. Second, the imposition of Pigouvian taxes provides greater incentives to resource users to explore resource-saving technological improvements. This is because if the users are taxed, they pay more for the resource than they would have if they had been issued quotas instead. Third, environmental taxes, when properly designed, remove market distortions. In addition, there is a presumption that tax revenues, thus collected, would enable the government to reduce distortingary taxes (e.g., taxes on earned income). There is thus a presumption that Pigouvian taxes yield a “double dividend” (Bovenberg and van der Ploeg, 1994; Goulder, 1995; Bovenberg and Goulder, 1996; but see Bohm, 1996), a rhetorical phrase that has been much used in recent years to persuade governments to impose “green” taxes. Matters of public finance have been a recurrent theme in ecological economics (Baumol and Oates, 1975; Cropper and Oates, 1992; Carraro and Siniscalco, 1996).4

III. INSTITUTIONAL FAILURES AND POVERTY: GLOBAL VS LOCAL ENVIRONMENTAL PROBLEMS

Thus far, market failure. Recently, however, certain patterns of environmental deterioration have been traced to government failure. For example, Binswanger (1991) argued that, in Brazil, the exemption from taxation of virtually all agricultural income (allied to the fact that logging is regarded as proof of land occupancy) has provided strong incentives to the rich to acquire forest land and to then deforest it. He argued that the subsidy the government has thereby provided to the private sector has been so large that a reduction in deforestation (via a removal of subsidies) is in Brazil’s interests and not merely in the interest of the rest of the world. This has implications for international negotiations. The current consensus appears to be that, as a country, Brazil has much to lose from reducing the rate of deforestation in which it is engaged. If this were true, there would be a case for the rest of the world to subsidize Brazil, providing compensation for losses it would sustain if it were to restrain itself. However, as Binswanger’s account suggests, it is not clear if the consensus is correct.5 Elsewhere (and by extension), one would imagine that the massive agricultural subsidies in the European Union considerably influence agricultural practices in ways that inflict substantial damage on the environment.

However, it is important to note that the causes of environmental problems are not limited to market and government failure; problems also occur because such microinstitutions as the household can function badly. In poor communities, for example, men typically have the bulk of the political voice. We should then expect public investment in, for example, resource regeneration to be guided by male preferences, not female needs. On matters of afforestation in the drylands, for instance, we should expect women to favor planting for fuelwood and men for fruit trees because it is the women and children who collect fuelwood, whereas men control cash income (and fruit can be sold in the market). This explains why, even as the sources of fuelwood continue to recede, fruit trees are often planted (Dasgupta, 1993).

That political instability (at the extreme, civil war) is a direct cause of resource degradation is obvious. What is not obvious is that it is a hidden cause as well. Political instability creates uncertainty in property rights. In its presence, people are reluctant to make investments that are necessary for environmental protection and improvement. The expected returns on such forms of investment are low. In a study comprising 120 countries, Deacon (1994) offered statistical evidence of a positive link between political instability and forest depletion.

Together, these examples reflect the environmental consequences of institutional failure. They have a wide reach, and in recent years they have often been discussed within the context of the thesis that environmental degradation, such as eroding soil, receding forests, and vanishing water supplies, is a cause of accentuated poverty among the rural poor in poor countries. There is truth in this. However, there is also accumulated

4 A hybrid policy instrument, which involves the government issuing a fixed number of transferable licenses, combines some of the features of quotas and Pigouvian taxes. For example, the scheme resembles quotas in that resource rents are not captured by government, and it resembles Pigouvian taxes in that the margin license holders pay the accounting price of the resource for its use. See Tietenberg (1980, 1990) for a discussion of transferable licenses, both in theory and in practice.

5 In a broader discussion of the conversion of forests into ranches in the Amazon basin, Schneider (1995) demonstrated that the construction of roads through the forests has also been a potent force.
evidence that poverty can be a cause of environmental
degradation (Dasgupta and Mäler, 1991, 1995; Das-
gupta, 1993a, 1999; Ehrlich et al., 1995). This reverse
causality occurs because some natural resources (e.g.,
ponds and rivers) are essential for survival in normal
times, whereas others (e.g., forest products) are also
a source of supplementary income in times of acute
economic stress. In changing circumstances (e.g., eco-
omic development in urban centers), social norms
which previously had maintained long-term economic
relationships among members of a community tend to
break down. Some (e.g., the able-bodied and mobile)
gain, whereas others (e.g., women, the old, and the very
young) lose and become poorer. In extreme cases, the
breakdown of social norms also means that local re-
sources which earlier were subject to communitarian
regulations become "open access," with all the at-
tended consequences.

These links between rural poverty and the state of
the local natural resource base in poor countries offer
a possible pathway along which poverty, resource degrada-
tion, and even high fertility feed on one another in
a synergistic manner over time (Dasgupta, 1993a,
1995, 2000). Recent experiences in sub-Saharan Africa
and Pakistan are not inconsistent with this (Cleaver and
Schreiber, 1994; Filmer and Pritchett, 1996). Indeed, an
erosion of the local natural resource base can make
certain categories of people destitute even while the
economy's gross national product increases. The belief
that entire populations can always be relied on to make
the shift from resource-based, subsistence existence to
a high-income, industrial one is belied both by evidence
and by theory.

These two causes of resource degradation (i.e., insti-
tutional failure and poverty) pull in different directions
and are together not unrelated to an intellectual tension
between the concerns people share about global warm-
ing and acid rains, which sweep across regions, nations,
and continents, and about those matters (e.g., the de-
cline in firewood or water sources) which are specific
to the needs and concerns of the poor in as small a
group as a village community. Environmental problems
present themselves differently to different people. In
part, it is a reflection of the tension previously discussed
and is a source of misunderstanding of people's atti-
dutes. Some people, for example, identify environmental
problems with poverty and unprecedented popula-
tion growth in the South, whereas others identify them
with wealth and unprecedented expenditure patterns
in the North (I use the geographical terms in their
current geopolitical sense). Even though debates be-
tween the two groups often become shrill, each vision
is in part correct. There is no single environmental
problem, and therefore no single valuation problem;
rather, there is a large collection of them (Dasgupta
and Mäler, 1995; Reardon and Vosti, 1995; Vincent et
al., 1997). Thus, growth in industrial wastes and re-
source use have been allied to increased economic activ-
ity; and in the former, Socialist block neither preventive
nor curative measures have kept pace with the produc-
tion of waste. Moreover, the scale of the human enter-
prise, both by virtue of unprecedented increases in the
size of the world's population and by the extent of
economic activity, has so stretched the capabilities of
ecosystems that humankind can today rightly be charac-
terized as Earth's dominant species (Vitousek et al.,
1997). These observations loom large not only in eco-
logical economics but also in the more general writings
of environmentalists and in the professional writings
of ecologists in the West.

On the other hand, economic growth has brought
with it improvements in the quality of many natural
resources. The large-scale availability of potable water
and the increased protection of human populations
against both water- and air-borne diseases in industrial
countries have in great measure occurred in the wake of
growth in national income these countries have enjoyed
during approximately the past 200 years. Moreover, the
physical environment inside the home has improved
beyond measure with economic growth. For example,
cooking in Southeast Asia continues to be a central
route to respiratory illnesses among women. Such pos-
tive links between economic growth and environmental
quality often go unnoted by environmentalists in the
North. I believe that this lacuna is another reflection
of the fact that it is easy to overlook the enormous
heterogeneity of Earth's natural resource base, ranging
from the atmosphere, oceans, and landscapes to water
holes, grazing fields, and sources of fuelwood. Both this
heterogeneity and the diversity of the human condition
throughout the world need constantly to be kept in
mind in discussions of the value of biodiversity in differ-
et locations.

IV. VALUING RESOURCES AND
EVALUATING PROJECTS

Since institutional failures abound in our dealings with
Earth, the commercial profitability of economic activi-
ties, for example, of investment projects (projects for
short), is frequently not an adequate measure of their
social worth. Therefore, recourse should be taken to
social cost–benefit analysis, the purpose of which is to estimate the impact of projects on human well-being, now and in the future. Note that, if undertaken, a project would be a perturbation to the economy. Therefore, a project consisting of the construction of a dam, for example, would be a perturbation to an economy without the dam. The economic forecast sans the project can be thought of as the status quo.

Analyzing the consequences of a project would involve estimating the need for labor, intermediate products, raw materials, and output as well as predicting the ecological effects of the project. These consequences need to be specified for each future period (see Section VII for a formalization). Since there is never sufficient knowledge to make precise estimates of the consequences, project evaluators should quantify estimates of the uncertainties, preferably in terms of probabilities. This means that, in general, project designers should model the integrated ecological and economic system. However, in practice this is infrequently done.6

In order to derive a good estimate of a project’s social benefits and costs, one should in principle value every commodity involved in it. The procedure devised by economists is to select some readily measurable bundle of goods ordinarily consumed and define the value of any other commodity as the amount of the bundle society would be willing to give up for it. This is a workable way for estimating the commodity’s accounting price. The net social benefit of a project in any given period of its life is obtained by multiplying the project’s inputs and outputs in that period by their corresponding accounting prices and adding them (outputs of “goods” are taken to be positive, and output of “bads” and inputs are taken to be negative). Using a suitable discount rate (often called the social discount rate; Arrow et al., 1996; Portney and Weyant, 1999), the net social benefits yielded by a project in each period are added. Projects which yield a positive present discounted value of net social benefits are recommended for acceptance, whereas those yielding a negative present discounted value of net social benefits are rejected. The theory of social cost–benefit analysis has been developed by economists during the past 50 years and is now, to all intents and purposes, complete (Dasgupta et al., 1972; Little and Mirrlees, 1974; Dasgupta and Maler, 2000).7

A prior exercise (i.e., prior to conducting social cost–benefit analysis) is to estimate accounting prices. A great deal of work in ecological economics has been directed at discovering methods for estimating accounting prices of natural resources.

It must be remembered that the kinds of resources I am considering here are sometimes of direct use in consumption (as with fisheries), sometimes of indirect use as inputs in production (as with plankton, which serves as food for fish), and sometimes both (as with drinking and irrigation water). The value may be utilitarian (e.g., as a source of food or a keystone species), it may be aesthetic (e.g., a shoreline), or it may be intrinsic; indeed, it may be all these things.

Economists have devised various methods for estimating accounting prices. As would be expected, the prices of some natural resources are easier to estimate than those of others. There are standard techniques for determining the accounting prices of irrigation water, fisheries, timber, and agricultural soil (Anderson, 1987; Repetto et al., 1989; Solorzano et al., 1991; Vincent et al., 1997). They involve estimating the resource’s use value. For example, the value of a piece of agricultural land, such as agricultural land, would be the present discounted value of the flow of net profits it is expected to generate from cultivation minus the environmental damage caused by the pesticides and herbicides to be used. Such an approach can also be used for estimating losses associated with water-logging and overgrazing. Reductions in air- or water-borne pollution can be valued in terms of improvements in health (e.g., reductions in the number of days people would be expected to be ill, World Bank, 1992). Other techniques have been devised for valuing “amenities” such as places of scenic beauty.8

Methods have also been devised for giving expression to the “precautionary principle,” which assumes a particularly subtle form when applied to resources such as genetic material in tropical forests. The subtlety arises from a combination of uncertainty in the future use values of these resources and irreversibility when they are lost. The twin presence of uncertainty and irrevers-

6 However, there are signs of change. See, for example, Perrings et al. (1994, 1995), Vincent et al. (1997), Chopra and Kadkoohi (1999), and various issues of the journal Environment and Development Economics.

7 Dally et al. (1999) provide a nontechnical account of the role of social cost–benefit analysis in environmental management.

8 One popular method involves asking people hypothetical questions concerning their willingness to pay for preserving the amenity (this is called the “contingent valuation method”); another involves estimating from sample surveys the distribution of costs that visitors from different locations have incurred to view the site (this is called the “travel cost method”). A third involves inferring how much people are willing to pay for enjoying the amenity (e.g., clean air) from the commercial value of land at sites which offer the amenity (this is called the “hedonic price” of land). See Maler and Wycka (1976), Mitchell and Carson (1989), and Freeman (1992).
ibility implies that preservation of the stock has a value in addition to its current use value, namely, the value of extending society's set of future options. Future options have an additional worth because, with the passage of time, more information is expected to be forthcoming about the resource's use value. This additional worth is often called an option value (Arrow and Fisher, 1974; Henry, 1974; Fisher and Hanemann, 1986). The accounting price of a resource, at the very least, is the sum of its direct use value and its option value.

These techniques enable us to estimate the use value of a given resource. The resource's accounting price may well exceed this. Why? Because there may be additional values "embodied" in a resource. An additional consideration is applicable to living resources: their intrinsic worth as living resources. It would be absurd to suppose that the value of a blue whale is embodied entirely in its flesh and oil, or that the value of game in Kenyan safari parks is simply the present discounted value of the flow of tourists' willingness to pay to view them. The idea of intrinsic worth of living things is inherent not only in traditional religious systems of ethics but also in modern ethical theories. Therefore, the question is not so much whether living creatures have intrinsic worth but rather regards the ways of assessing this worth. Because it is almost impossible to get a quantitative handle on intrinsic worth, the correct thing to do is to take note of it, keep an eye on it, and call attention to it in public debate if the stock is threatened with destruction.

We may conclude that the social worth of natural resources can be divided into three parts: their use value, their option value, and their intrinsic value. The components appear in different proportions, depending on the resource. For example, oil and natural gas would not be thought to have intrinsic value, nor perhaps an option value, but they have use value. On the other hand, primates would be thought to be intrinsically valuable.

It must also be emphasized that the purpose of estimating environmental accounting prices is not to value the entire environment; rather, it is to evaluate the benefits and costs associated with changes made to the environment due to human activities. Prices, whether actual or accounting, have significance only when there are potential exchanges from which choices have to be made (e.g., when one has to choose among alternative investment projects). Thus, the statement that a particular act of investment can be expected to degrade the environment by, for example, $1 million annually has meaning because it says, among other things, that if the investment were not to be undertaken, humanity would enjoy an additional $1 million of annual benefits in the form of environmental services. The statement also has operational significance: The estimate could (and should) be used for calculating the rate of return attributable to the investment in question.

Contrast such an estimate of the value of an incremental change in the natural resource base with the one which says that, worldwide, the flow of environmental services is currently worth, in total, $33 trillion annually (Costanza et al., 1997). The former is meaningful because it presumes that humanity will survive the incremental change and be there to experience and assess the change. The reason the latter should cause us to balk is that if environmental services were to cease, life would not exist. However, who would be there to receive $33 trillion of annual benefits if humanity wished to exchange its very existence for them? This is a case in which the value of an entire something has no meaning and therefore is of no use, even though the value of incremental changes to that same something not only has meaning but also has use.

V. BIODIVERSITY: NECESSITY OR LUXURY?

Biodiversity has been neglected in economics. Scratch an economist, and you are likely to find someone who regards the natural resource base as an "amenity." Thus, it is commonplace that, to quote a recent editorial in London's Independent (December 4, 1999), "[economic] growth is good for the environment because countries need to put poverty behind them in order to care" or that, to quote the Economist (December 4, 1999, p. 17), "trade improves the environment, because it raises incomes, and the richer people are, the more willing they are to devote resources to cleaning up their living space."

I quote these views not to question that poverty should be a phenomenon of the past, nor to suggest that arbitrary restrictions on trade do not cause much harm, but rather to show that natural resources are widely viewed as luxuries. This is, of course, an incorrect view: The natural resource base is not a luxury. Producing, as it does a multitude of ecosystem services, the natural resource base is a necessity. Indeed, the

---

* As stressed elsewhere in the encyclopedia, these services include maintaining a genetic library, preserving and regenerating soil, recycling nutrients, controlling floods, filtering pollutants, assimilating waste, pollinating crops, operating the hydrological cycle, and maintaining the gaseous composition of the atmosphere.
ECOLOGICAL ECONOMICS TO BE FOUND IN THE NORTH DOES NOT EXACTLY RESONATE AMONG THOSE WHO Worry ABOUT DEGRADATION OF THE NATURAL RESOURCE BASE IN THE SOUTH AND THE ADDITIONAL HARDSHIP THIS BRINGS TO THE MANY AMONG THE POOREST OF PEOPLE WHOSE LIVES DEPEND DIRECTLY ON THAT BASE. NEEDLESS TO SAY, IT DOES NOT RESONATE AMONG ECOLOGISTS, QUÀ ECOLOGISTS, EITHER.

This perspective of viewing natural resources as luxuries is expressed in the World Bank (1992) report, in which it was suggested that there is an empirical relationship between gross domestic product (GDP) per head and concentrations of industrial pollutants. Based on the historical experience of the Organization for Economic Cooperation and Development countries, it was argued in the document that, when GDP per head is low concentrations of atmospheric pollutants [e.g., sulfur dioxide (SO₂)] increase as GDP per head increases, but when GDP per head is high concentrations decrease as GDP per head increases further. In other words, it was found that the functional relationship between GDP per head and concentrations of industrial pollutants has an inverted U shape (Fig. 1). Among economists, this relationship has been christened the "environmental Kuznets curve".¹¹

Panayotou (1992) reported the inverted U shape in cross-country data on GDP per head and deforestation and emissions of SO₂, nitrogen oxides (NOₓ), and particulate matters. Sweden, for example, was found to lie on the downward part of the curve. Indeed, time series on timber stocks and sulfur and nitrogen emissions in Sweden, during the 1980s, are consistent with this: Timber stocks have increased, and the emission rates of sulfur and nitrogen oxides have declined.

Note that, excluding forests (but see Section VI), the previously mentioned findings concern mobile pollutants. Their mobility hides the fact that earlier emissions have had to find somewhere to lodge: Since matter is conserved, inputs and outputs of material must balance (Ayres and Kneese, 1969; d'Arge et al., 1970; Mäler, 1974). The point is that my emissions would affect not only me but also you if you lived downstream or downstream. However, even if we did not consider this point, the logic underlying the environmental Kuznets curve is that resource degradation is reversible: Degradation all you want now, you can always recover the stock later because Earth can be relied on to rejuvenate it. The science of biodiversity has shown this presumption to be false. The presence of ecological thresholds implies that damage to ecosystems can be irreversible. As an overarching metaphor for "trade-offs" between manufactured wealth and resource degradation, the environmental Kuznets curve has to be rejected.¹²

VI. SUBSTITUTION POSSIBILITIES¹³

The belief that constraints arising from resource depletion can be overcome as countries become wealthier in terms of their manufactured and human capital assets is frequently based on a subtler idea than the one that underlies the environmental Kuznets curve. The belief is based on possibilities of substitution.

Resource constraints facing an economy can be eased by four types of substitution. First, there can be substitution of one thing for another in consumption (nylon and rayon cloth substituting for cotton and wool, pulses substituting for meat, etc.). Second, manufactured capital can substitute for labor and natural resources in production (the wheel and double-glazing are two extreme examples). Third, novel production techniques can substitute for old ones. For example, the replacement of the piston with the steam turbine (i.e., converting from reciprocating to rotary motion) was introduced into power plants and ships more than 100 years ago. The innovation was an enormous energy saver in engines. Fourth, and most important, natural resources

¹¹ I have discussed these concerns in greater detail elsewhere (Dasgupta, 1982, 1993a, 1996, 1997).

¹² This is a misnomer. The original Kuznets curve, which was an inverted U, related income inequality to real national income per head on the basis of historical cross-country evidence.

¹³ For more extensive discussion of the environmental Kuznets curve, see Arrow et al. (1995) and the responses their article elicited in symposia built around the article in Ecological Economics 15 (1995), Ecological Applications 6 (1996), and Environment and Development Economics 1 (1996); also see the special issue of Environment and Development 2(4) (1997).

¹⁴ This and the following section are based on Dasgupta and Mäler (1999) and Dasgupta et al. (2000a,b).
can substitute for one another. This involves the belief that, as each resource (e.g., each species) is depleted, there are similar substitutes lying in wait, either at the same site or elsewhere. If this were true, then even as constraints increasingly tighten on any one resource base, humanity would be able move to other resource bases, either at the same site or elsewhere. The enormous additions to the sources of industrial energy that have been realized (successively, human and animal power, wind, timber, coal, oil, and natural gas and, recently, nuclear) are a prime historical illustration of this possibility.14

Humans have been "substituting" one thing for another since time immemorial. Even the conversion of forests into agricultural land in England in the Middle Ages was a form of substitution: Large ecosystems were transformed to produce more food. However, the pace and scale of substitution in recent centuries have been unprecedented. Landes (1998) argued that substitution created the industrial revolution in England in the eighteenth century. The extraordinary economic progress experienced in Western Europe and North America since then (during the past two centuries GDP per head in Western Europe has increased approximately 20-fold), and recently in East Asia, has also been a consequence of substitution. Spatial dispersion of ecosystems has enabled this to happen. The ecological transformation of rural England in the Middle Ages presumably reduced the nation's biodiversity, but it increased income without any direct effect on global productivity.

However, that was in the past, and we must deal with the present. A question currently much debated is whether it is possible for the scale of human activity to be increased substantially beyond what it is today without placing undue stress on the major ecosystems that remain. In any event, the cost of substituting manufactured capital for natural resources can be high. Low-cost substitutes could turn out to be not so low-cost if accounting prices were used in the costing, not market prices. Even when accounting prices are not used, degrading natural capital and substituting it with manufactured capital can be uneconomic. Chichilnisky and Heal (1998) compared the costs of restoring the ecological functioning of the Catskill watershed ecosystem in New York State to the costs of replacing the natural water purification and filtration services the ecosystem has provided in the past by building a water-purification plant costing $8 billion. They showed the overwhelming economic advantages of preservation compared to construction: Independent of the other services the Catskill watershed provides and ignoring the annual running costs of $300 million for a filtration plant, the capital costs alone showed a more than sixfold advantage for investing in the natural capital base.

Degradation of a natural resource base (e.g., destruction of native populations of flora and fauna) not only affects the volume and quality of ecosystem services the base provides but also challenges the system's resilience, which is its capacity to absorb disturbances, or perturbations, without undergoing fundamental changes in its functional characteristics. The way to interpret an ecosystem's loss of resilience is to view it as having moved to a new stability domain, which is another way of saying that the system, having crossed a threshold, has been captured by a different attractor (Levin et al., 1998; Levin, 1999; Brock et al., 1999). Sudden changes in the character of shallow lakes (e.g., from clear to eutrophied water), owing to increases in the input of nutrients (Schuster, 1997; Carpenter et al., 1998), and the transformation of grasslands into shrublands, consequent upon nonadaptive cattle management practices (Perring and Walker, 1995), are examples. Human societies have on occasion been unable to avoid suffering from unexpected changes in their local ecosystems. Fishermen on Lake Victoria and the nomads in the now shrublands of southern Africa are examples from recent years.

Biodiversity appears to be a key to ecosystem resilience. However, even today it is a popular belief that the utilitarian value of biodiversity is based mainly in the potential uses of genetic material (e.g., for pharmaceutical purposes) or, in other words, that its social worth is almost wholly an option value. Preservation of biodiversity is seen as a way to hold a diverse portfolio of assets with uncertain payoff. However, as other contributions to this encyclopedia make clear, biodiversity, appropriately conceived, is essential for the maintenance of a wide variety of services on which humans depend for survival. This has the important corollary that to invoke the idea of substitutability among natural resources in order to play down the use value of biodiversity, as people frequently do (Simon, 1981, 1994), is a wrong intellectual move. The point is that if an ecosystem's biodiversity is necessary for it to be able to continue providing us with its services, the importance of that same biodiversity cannot be downplayed by the mere hope that for every species there are substitute

14 However, these shifts have not been without unanticipated collective costs. Global warming, associated with the burning of fossil fuels (an "externality"), did not feature in economic computations in earlier decades. See Dasgupta (1993b) for a less coarse partition of substitution possibilities than that provided by the four-way classification.
species lying in wait within that same ecosystem. In other words, there is an inconsistency in this line of reasoning. Recall the famous analogy in Ehrlich and Ehrlich (1981) relating species in an ecosystem to rivets in an airplane. One by one, perhaps, species may disappear and not be missed. Eventually, however, the cumulative effect of loss of biodiversity will lead to the crash of ecosystem functioning, just as the cumulative loss of redundant rivets will lead to the crash of an airplane.

VII. ECOSYSTEM BIFURCATIONS AND DISCONTINUOUS VALUE FUNCTIONS

How do discontinuities in the social worth of ecosystems affect valuation exercises and social cost–benefit analysis? To answer this, it helps to formalize.

Consider an ecosystem describable by N state variables, indexed by i and j (i, j = 1, 2, …, N). For concreteness, we may think of each state variable as reflecting the population size of a particular species. (As noted in Section I, problems of environmental pollution can be formulated in a similar manner.) Denote time by t (≥0) and let $S_i$ be the population size of i at t. Time is taken to be a continuous variable. We imagine, therefore, that the dynamics of the ecosystem can be described by a system of (nonlinear) differential equations. For expositional ease, we assume that the system is deterministic.

Let the net reproduction rate of i at t be $F_i$. Since the ecosystem is coupled, $F_i$ is a function of the stocks at t. Thus I write as $F_i(S_{1i}, S_{2i}, \ldots, S_{Ni})$, for i = 1, 2, …, N. I assume that ecologists have estimated these functions. Next, assume that the ecosystem dynamics are autonomous. This means that $F_i$ is not an explicit function of t. Therefore, I drop the subscript t from $F_i$ and write the function as $F_i(S_{1i}, S_{2i}, \ldots, S_{Ni})$. In all the applications of this framework with which I am familiar, $F_i$ is taken to be a differentiable function. Let us assume this is true.

The analysis begins at t = 0 (the "present"). Denote by $X_i$ the rate at which species i is harvested at time t. We now imagine that economists have studied the human–ecosystem interactions in question. They have inquired into the structure of property rights, demand conditions, government policies, and so forth. On the basis of this they have concluded that harvests are based on an implicit policy, in that they are time autonomous and are functions solely of stocks. Therefore, we may write $X_i = X_i(S_{1i}, S_{2i}, \ldots, S_{Ni})$. Assume that $X_i$ is piecewise continuous and possesses right and left partial derivatives everywhere. This is a technical assumption and a good one. For example, optimal policy functions for those ecosystem management problems that have been studied have been found to possess this property (Skiba, 1978; Brock et al., 1999). Moreover, actual harvest rates have frequently been known to be approximately constant over time. Both sets of examples satisfy the assumption.

No doubt some of the $X_i$’s would be zero. For example, it could be that only one species in the ecosystem is ever harvested (e.g., because it is the only one that has economic worth). We should think of $X_i$ as a forecast. It should be stressed that $X_i(S_{1i}, S_{2i}, \ldots, S_{Ni})$ is not necessarily a socially optimal harvest policy function. It can be an actual policy function within an imperfect institution (e.g., the ecosystem could be one to which there is free access).

The rate of change of $S_i$ is the difference between $F_i$ and $X_i$. Therefore, given the economists' forecast for $X_i$, mathematicians would be able to forecast $S_i$ by solving the "coupled" system of differential equations:

$$\frac{dS_i}{dt} = F_i(S_{1i}, S_{2i}, \ldots, S_{Ni}) - X_i(S_{1i}, S_{2i}, \ldots, S_{Ni}), \text{ for all } i$$

(1)

For simplicity of exposition, assume that the social worth of the ecosystem is autonomous in time. We may then express that worth by a scalar V. Since V would be a function of the stocks, we may write it as $V(S_{1i}, S_{2i}, \ldots, S_{Ni})$. V is the value at t of the entire ecosystem. It is the maximum amount society should be "willing to pay" at t for the ecosystem's survival if the stocks of the N resources were $S_{1i}, S_{2i}, \ldots,$ and $S_{Ni}$, respectively. Any alternative use of the site (e.g., conversion into an urban center) would have to be worth at least V if the alternative were to be acceptable. The form of V would depend on the availability of substitutes for those species that are harvested. Again, to keep the mathematical notation from becoming too complex, I assume that there are no substitutes available at low cost from outside the ecosystem (e.g., because the community doing the harvesting is not near other sources of livelihood). Using Eq. (1), it is possible to use the forecast on harvest rates to determine forecasts on stocks. This in turn makes it possible to forecast the time path of V.

10 Actual harvest rates frequently display time trends, for example, because population and income grow. Time trends in $X_i$ would render the system of Eq. (1) below nonautonomous. In the text, I restrict the discussion to autonomous systems because I understand the mathematics of autonomous better than that of nonautonomous ones. However, experience with simple nonautonomous systems suggests that the arguments I offer later in the text apply to them as well.
At one level the valuation problem is now "solved": \( V(S_1, S_2, \ldots, S_n) \) would be the value of the ecosystem at \( t \). It would be the social worth of the ecosystem at \( t \). The problem is that \( V \) is typically a nonlinear function, which means that it is very difficult to estimate. The task of valuing ecosystems would be made much easier if recourse were taken to estimating accounting prices. The advantage would be that since accounting prices reflect the social worth of marginal units of the various populations, we could use such prices to construct a linear index of the ecosystem's value.

Assume that \( V \) is differentiable everywhere. Let \( P_i \) be the accounting price of \( i \) at \( t \). From the discussion in Section IV and from our assumption that no substitutive resources are near the human community in question, we know that

\[
P_i = \partial V / \partial S_i, \text{ for all } i \text{ and all } t
\]

(2)

At time \( t \) the value of species \( i \) would be \( P_i S_i \). It follows that the value of the ecosystem would be \( \sum P_i S_i \). Note that this is a linear function of stocks, with the weights being accounting prices.

In Section IV it was noted that a "project" can be thought of as a perturbation of the forecast \( X_n \). Therefore, a project can be denoted as \( (\Delta X_1, \Delta X_2, \ldots, \Delta X_n) \), for \( t \geq 0 \). (\( \Delta \) denotes an operator signifying "small difference.") Some of the \( \Delta X_i \)'s would be zero. Nevertheless, the project would be expected to perturb future stocks of all the resources since this is what a strongly coupled ecosystem would be expected to display.

Let \( r \) be the social rate of discount and let \( C_i \) be the unit cost of harvesting \( i \) at \( t \). \(^{18} \) It follows that the present discounted value of the flow of net social benefits from the project is

\[
o^t \sum e^{-rt} \left[ \sum (P_i - C_i) \Delta X_i \right] dt
\]

(3)

If Eq. (3) is positive, the project should be accepted; if it is negative, the project should be rejected.

It can be argued that projects, as I have defined them here, are merely "small" perturbations, whereas redirecting economic activity so as to avoid damaging an ecosystem irrevocably could involve drastic change. However, it should be noted that one way to conceptualize a "large" perturbation is to regard it as the sum of many small perturbations. A large perturbation (i.e., a large project) could then be evaluated by repeated use of Eq. (3).

However, if this route is not adopted, social cost-benefit analysis of large projects requires the project evaluator to estimate the large changes in \( V \) consequent on the adoption of large changes in economic policy. Accounting prices, reflecting the social worth of marginal units of the various resources (Eq. 2), would then not suffice. The evaluator would need to integrate over the marginal units so as to estimate "consumer surpluses," to use a term familiar in economics.

So far so good. However, there is a problem with the account: It is unreasonable to assume that \( V \) is differentiable, even continuous, everywhere. Ecosystems are nonlinear. So, even if it were reasonable to suppose that \( V \) is differentiable everywhere else, it would be wrong to suppose that it is even continuous at separatrixes and bifurcation points.\(^{19} \)

However, if the \( X_i \)'s are not optimal, \( V \) can be discontinuous at points on separatrixes and bifurcation points. This causes problems because accounting prices cannot be defined at such points. Now, we will study the implications of this for biodiversity valuation and social cost-benefit analysis.

Experience with nonlinear models of ecosystems tells us that, under the assumptions we have made, there could be at most a countable number of bifurcation points and separatrixes. This is fortunate because it means that points on the stock space that are "troublesome" are nongeneric. Therefore, let us assume this is so. In Fig. 2, the matter is illustrated in the context of an ecosystem comprising a single species. Figure 2 depicts the case in which the separatrix is a single point, \( S^* \), reflecting a threshold. For example, it could be that, under the harvesting policy \( X(S) \), the species would become extinct if its population were below \( S^* \) but would be harvested in a sustainable manner if the population were in excess of \( S^* \). Therefore, stocks to the

---

\(^{18} \) If substitutes were available, \( P_i \) would be the minimum of \( \partial V / \partial S_i \) and the accounting price of the substitute. I want to avoid such complications here.

\(^{17} \) Note that for all \( i \) and all \( t \), \( \Delta X_i = \sum (\partial X_i / \partial S_i) (dS_i/dt) \Delta t \).

\(^{16} \) \( C_i \) could depend on stock sizes at \( t \). For example, the unit cost of fishing depends not only on the technology available for fishing and the price of fishing equipment but also on the stock in the fishery. The larger the stock, the smaller the unit cost.

\(^{19} \) The location of bifurcation points depends on, among other things, the \( X_i \)'s. Therefore, they are endogenous to the economic-ecological system. In an important early contribution, Skiba (1978) showed via an example that if harvest functions are optimal, \( V \) is continuous even at points where harvests are discontinuous. This means that accounting prices are not uniquely specified at such points. However, \( V \) can be shown to possess right- and left-partial derivatives there. Therefore, accounting prices can be used for evaluation purposes, even though they are not uniquely given at every point on the space of resource stocks.
right and left of $S^*$ represent different basins of attraction. Figure 2 reasonably depicts a case in which the value of the species, $V(S)$, is an increasing function of the stock. It is assumed to be continuous (indeed, differentiable) everywhere except at $S^*$, where it jumps (an irreversibly dying population being a lot less valuable than a sustainable one). Of course, the location of $S^*$ depends on $X(S)$: Change the harvesting policy slightly, and $S^*$ will shift slightly. The influence of $X(S)$ on $S^*$ has to be estimated if ecologists and economists are to offer policy advice.

Now, excepting by fluke, the stock at $t = 0$ would be different from $S^*$. Therefore, let us assume it is different. If the project is sufficiently small, the account of social cost–benefit analysis given previously remains valid: The system would not cross into a different basin of attraction. However, a good theory should be extendable to fluke cases. Moreover, actual projects are frequently not “small” so that acceptance of a project or its rejection could mean that the ecosystem is eventually in one basin of attraction rather than in another. How do we extend the theory to handle the possibility that the ecosystem crosses into a different basin of attraction? In particular, is the repeated use of Eq. (3) a feasible means of evaluating projects?

It is also clear where the problem lies if we try using Eq. (3). The problem lies in that an accounting price cannot be defined at $S^*$. This means that a project which involves the stock passing through $S^*$ cannot be evaluated by means of a linear index of social profitability. The height of the jump would have to be estimated and put to use in social cost–benefit analysis. Ecologists and economists would have to combine their expertise to locate $S^*$ and identify the functional form of $V(S)$, both on the right and on the left of $S^*$. Estimating the height of the jump involves measuring consumer surpluses, a point noted earlier. In short, at least one small project in the series of small projects which add up to the large project in question would not be assessable by means of Eq. (3). This causes difficulties.

However, there is a way to avoid the problem. We have been studying deterministic systems. Introducing uncertainty about the location of $S^*$ can help matters by smoothing the value function. To see how, imagine that $V(S)$ represents the expected value of the resource's social worth at $S$. If the location of $S^*$ were a smooth probability distribution, $V(S)$ would be a continuous, even a differentiable, function. In this case, an accounting price of the resource would be definable at all $S$ (with $S^*$ being a smooth random variable). A linear index of the social profitability of projects could then be constructed. The methods of social cost–benefit analysis outlined earlier would remain valid.

It is not often that introducing realism simplifies analysis. Valuing biodiversity would seem to be an exception.

GLOSSARY

autotroph Literature, a self-feeder, an organism that is able to utilize inorganic carbon (carbon dioxide) as the sole carbon source for growth, for example, green plants and certain bacteria.

black box Entity that can be examined at the system level without specifying its internal contents.

heterotroph Literature, a feeder on others, an organism that is dependent on organic material from an external source to provide carbon for growth, for example, vertebrates.

industrialized agriculture Modern form of agriculture that differs from traditional agriculture in the use of elaborate and expensive machinery, the control of pests with toxic chemicals rather than biocontrols, fertilization by synthetic rather than organic products, excessive consumption of water, and farm ownership and management by corporations rather than individuals.

input environment Collective term for all energy and materials moving into a given system.

mega-city Modern city with a large, expanding population, characterized by high consumption levels of energy, water, and food from sources outside the city.

output environment Collective term for all energy and materials moving out of a given system.

 techno-ecosystem Technology-based ecosystem in the contemporary world that is fundamentally distinct from natural ecosystems in the use of energy sources other than sunlight (fossil fuels, nuclear power), an urbanized concentration of human population, and the generation of substantial amounts of air and water pollutants and waste materials.

LIVING ORGANISMS AND THEIR NONLIVING (ABIO- TIC) ENVIRONMENT are inseparably interrelated and interact with each other. An ecological system, or ecosystem, is any unit (a biosystem) that includes all the organisms (the biotic community) in a given area interacting with the physical environment so that a flow of energy leads to clearly defined biotic structures and cycling of materials between living and nonliving parts. An ecosystem is more than a geographical unit (or ecoregion); it is a functional system unit with inputs and outputs, and with boundaries that can be either natural or arbitrary.

I. INTRODUCTION

The ecosystem is the first unit in the molecule to ecosphere hierarchy (as shown in Fig. 1) that is complete,
that is, it has all the components, biological and physical, necessary for survival. Accordingly, it is the basic unit around which to organize both theory and practice in ecology. Furthermore, as the shortcomings of the "piecemeal" short-term technologic and economic approaches to dealing with complex problems become ever more evident with each passing year, management at this level, that is, ecosystem management, emerges as the challenge for the future.

Since ecosystems are functionally open systems, consideration of both inputs and outputs is an important part of the concept, as shown in Fig. 2. A diversity of species and genetic forms, together with a variety of functions and niches, are essential properties of natural ecosystems. Ecosystem diversity provides redundancy in times of environmental uncertainty.

II. THE ECOSYSTEM CONCEPT

The term "ecosystem" was first proposed in 1935 by the British ecologist A. G. Tansley, but of course the concept is by no means so recent. Allusions to the idea of the unity of organisms and the environment (as well as the oneness of humans and nature) can be found as far back in written history as one might care to look. Not until the late 1800s did formal statements begin to appear, interestingly enough, in a parallel manner in the American, European, and Russian ecological literature. Thus, in 1877 Karl Mobius wrote (in German) about the community of organisms in an oyster reef as a "biocoenosis," and in 1887 S. A. Forbes, an American, wrote his classic essay on the lake as a "microcosm." The pioneering Russian V. V. Dokuchaev and his chief disciple, G. F. Morozov (who specialized in forest ecology), emphasized the concept of the "biocoenosis," a term later expanded by Russian ecologists to "geobio-coenosis" (Sukachev, 1959).

In addition to biologists, physical scientists and social scientists began to consider the idea that both nature and human societies function as systems. In 1925, the physical chemist A. J. Lotka wrote in a book entitled *Elements of Physical Biology* that the organic and inorganic worlds function as a single system to such an extent that it is impossible to understand either part without understanding the whole. It is significant that a biologist (Tansley) and a physical scientist (Lotka) independently and at about the same time came up with the idea of the ecological system. Because Tansley coined the word "ecosystem" and it caught on, he gets most of the credit, which should be shared with Lotka.

In the 1930s, social scientists developed the holistic concept of regionalism, especially Howard W. Odum,
who used social indicators to compare the southern region of the United States with other regions (Odum, 1936; Odum and Moore, 1938). More recently, Machlis et al. (1997) and Force and Maddie (1997) have promoted the idea of the human ecosystem that combines biological ecology and social theories as a basis for practical ecosystem management. Accordingly, the concept of the ecosystem now brings together organisms, the physical environment, and humans.

As shown in Fig. 2, a graphic model of an ecosystem can consist of a box that we can label the system, which represents the area we are interested in, and two large funnels that we can label input environment and output environment. The boundary for the system can be arbitrary (whatever is convenient or of interest), delineating an area such as a block of forest or a section of beach, or it can be natural, such as the shore of a lake where the whole lake is to be the system, or ridges as boundaries of a watershed.

Energy is a necessary input. The sun is the ultimate energy source for the biosphere and directly supports most natural ecosystems within the biosphere. But there are other energy sources that may be important for many ecosystems, for example, wind, rain, water flow, or fuel (the major source for urban-industrial society). Energy also flows out of the system in the form of heat and in other transformed or processed forms such as organic matter (e.g., food and waste products) and pollutants. Water, air, and nutrients necessary for life, along with all kinds of other materials, constantly enter and leave the ecosystem. And, of course, organisms and their propagules (seeds and other reproductive stages) enter (immigrate) or leave (emigrate).

In Fig. 2 the system part of the ecosystem is shown as a "black box," which is defined by modelers as a unit whose general role or function can be evaluated without specifying its internal contents. Figure 3 is a graphic model of the solar-powered natural ecosystem showing internal system components and functions. The interactions of the three basic components, namely, (1) the community, (2) the flow of energy, and (3) the cycling of materials, are diagrammed in this simplified compartment model. Energy flow is one-way; some of the incoming solar energy is transformed and upgraded in

![FIGURE 3](image_url)
quality (i.e., converted into organic matter, a more upgraded form of energy than sunlight) by the community, but most of it is degraded and passes through and out of the system as low-quality heat energy (heat sink). Energy can be stored, then “fed back,” or exported, as shown in the diagram, but it cannot be reused. In contrast with energy, materials, including the nutrients necessary for life (carbon, nitrogen, phosphorus, and so on), and water can be used over and over again. The efficiency of recycling and the magnitude of imports and exports of nutrients vary widely with the type of ecosystem.

Each ‘box’ in Fig. 3 is given a distinctive shape that indicates its general function. Circles are renewable energy sources, bullets are autotrophs, hexagons are heterotrophs, and the round-bottomed shapes are storages (in this case of nutrients and organisms). The community is depicted as a ‘food web’ of autotrophs and heterotrophs linked together with appropriate energy flows, nutrient cycles, and storages.

Both graphic models (Figs. 2 and 3) emphasize that a conceptually complete ecosystem includes inputs and outputs along with the system as delimited, that is, an ecosystem = E + S + OE (input environment + system + output environment). This scheme solves the problem of where to draw lines around an entity that one wishes to consider, because it does not matter very much how the box portion of the ecosystem is delimited. Often, natural boundaries, such as a lakeshore or forest edge, or political ones, such as city limits, make convenient boundaries, but limits can just as well be arbitrary so long as they can be accurately designated in a geometric sense.

The box is not all there is to the ecosystem, because if the box were an impervious container, its living contents (lake or city) would die.

It is important to emphasize that it is the diversity of ecosystem functions including microbial recycling, inputs and outputs as well as habitats and human land uses that need to be maintained, not just the diversity of species or biodiversity in the narrow sense.

III. THE HUMAN-DOMINATED TECHNO-ECOSYSTEM

Current urban-industrial society not only impacts natural life-support ecosystems in negative and sometimes positive ways, but has created entirely new arrangements that we can call techno-ecosystems that are competitive with and parasitic on natural ecosystems. These human-made systems involve new, powerful energy sources, technology, money, and fuel-powered cities that have little or no parallel in nature. It is imperative that techno-ecosystems interface with natural life-support ecosystems in a more positive or mutualistic manner than is now the case if our rapidly growing urban-industrial society is to survive in a finite world.

Before the industrial revolution, humans were a part of—rather than apart from—natural ecosystems. In the ecosystem model of Fig. 3, humans functioned as top predators and omnivores (the terminal H box in the food web). Early agriculture, as is the case with traditional or preindustrial agriculture as still widely practiced in many parts of the world, was compatible with natural systems and often enriched the landscape in addition to providing food. But with the increasing use of fossil fuels and atomic fission—energy sources many times more powerful than sunlight—together with the mushrooming growth of cities and increasing use of money-based market economics as the basis for decision making, the model of Fig. 3 is no longer adequate. We need to create a new model for this techno-ecosystem, a term suggested by pioneer landscape ecologist Zev Naveh (1982).

Figure 4 is our graphic model for these new (in terms of human history) fuel-powered systems. It includes the four components listed earlier: powerful energy sources, technology, money, and cities. The model shows the inputs of the new fuel energy sources and natural resources, and the increasing outputs of air, water, and solid waste pollution that are very much larger and more toxic than anything that comes out of natural ecosystems. In Fig. 5 we add to the techno-ecosystem model some natural ecosystems that provide life-supporting goods and services (breathing, drinking, and eating!) and that maintain homeorhetic (i.e., pulsing) global balances in the atmosphere, soils, freshwater, and oceans. Note that money circulates as a two-way flow between society and human-made systems, but not natural systems, thereby creating a vast market failure when society fails to pay for ecosystem services.

A modern city,1 of course, is the major component of the fabricated techno-ecosystem. It is a very energetic hot spot that requires a large area of low-energy natural

---

1The term “city” is used synonymously with the geographers’ term “standard metropolitan district (SMD),” which includes industrial areas and residential suburbs that often extend far beyond official city limits.
FIGURE 4 A human-dominated techno-ecosystem.

FIGURE 5 A human-dominated techno-ecosystem and natural ecosystem.
and seminatural countryside to maintain it. Current
cities clean and recycle no air and or water (to the
point of being redrinkable), grow little or no food, and
generate a huge waste stream that impacts wide areas
of downstream rural landscapes and oceans. The city
does export money that pays for some natural resources,
and the city provides many desirable cultural instru-
cations, such as museums and symphonies, that are not
available in rural areas.

In summary, cities are essentially parasites on the
low-energy countryside. To call a city a parasite is not
to belittle it, but to be realistic. In undisturbed nature,
parasites and hosts tend to coevolve for coexistence;
otherwise, if the parasite takes too much from its host,
both die if the parasite has only one host. Currently
humans have only one habitable host—the earth.

Especially threatening to the global life-support eco-
systems is the explosive growth of mega-cities in the
less-developed nations, caused in part by the increasing
dominance of another techno-ecosystem, that of indus-
trialized agriculture, with its often excessive consump-
tion of water and use of toxic and enriching chemicals.
These systems produce more food products per unit of
space, but in turn are prodigious polluters and by their
economic might drive small farmers out of business
worldwide, forcing them into cities that are unable to
assimilate them. This current situation illustrates what
engineer and former president of MIT Paul Gray (1989)
has written: “A paradox of our time is the mixed blessing
of almost every technological development.” In other
words, technology has its destructive as well as benefi-
cial side. To bring the natural and technical ecosystems
into a mutualistic relationship will be society’s greatest
challenge in the twenty-first century.

GLOSSARY

aerobic In the presence of oxygen.
allochthonous Imported from outside the ecosystem.
biogeochemical Consisting of biological and abiotic transformations.
chemoautotrophy Use of energy-yielding chemical reactions as an energy source for synthesis of organic matter from inorganic precursors.
cohort A group of individuals of the same age that can be identified within a population.
compensation depth Depth where photosynthesis and respiration are in balance.
euphotic zone Water depth with sufficient light for photosynthesis.
photoautotrophy Use of light as an energy source for synthesis of organic matter from inorganic precursors.
plankton The community of organisms suspended in the water.
production Newly formed biomass of a population or trophic level, including the organic matter eliminated during the period of observation.
trophic level Position in a food chain, defined by the number of energy transfer steps to that level.
trophogenic region Region where net production of organic matter occurs by photoautotrophy or chemoautotrophy.
tropholytic region Region where respiration and decomposition of organic matter proceed in the absence of primary production.

INVESTIGATIONS OF ECOSYSTEM FUNCTION in fresh and saltwater have been dominated by two major themes. The themes originate in two different ways of thinking about biological production. Biological processes can be regarded fundamentally as conduits for the flow of mass and energy across trophic levels, or as the mechanisms by which individuals and populations maintain their existence. These processes include photosynthesis, mineral nutrient uptake, gathering of food, and extracting nutrition from it, as well as life history patterns, behavior, and survival strategies.

I. CONCEPTUAL FRAMEWORK

Investigation of biological mass flux and energy transfer relies on the first law of thermodynamics. Inquiries...
rooted in this theme require basic accounting for inputs and outputs balanced on carbon mass, nitrogen mass, or the chemically bound potential energy present in organic matter. The different bases for accounting are interlinked by the common stoichiometry of all protoplasm. As Alfred Redfield and his colleagues began to point out in the 1930s, there are consistent ratios among carbon, nitrogen, and phosphorus in living matter drawn from lakes and oceans. The ratios are not as rigid as the elemental composition of a crystalline mineral, but they are reliable within limits. They stem from the fact that organisms exist as biochemical aggregates of proteins, lipids, carbohydrates, and nucleic acids. The basic biochemical building blocks are universal, so the scope for differences among species is limited. If a class of organisms dominates the organic nitrogen pool within an ecosystem, it likely dominates in terms of organic carbon or calories as well. Thus the different measurement bases converge to common results.

The energy and mass-based approaches offer consistency of accounting, but they are intrinsically abiotic. They are indifferent to the forces that govern self-propagating genetic entities, for which the law of natural selection is as important as the laws of thermodynamics. Survival, persistence, and production of viable offspring are properties that define successful species, whether or not they dominate ecosystem biomass and material flux. An associated theme in measuring ecosystem function focuses on the properties of genetic entities rather than on the properties of conservation laws. This theme is keyed to the processes that add or subtract individuals within an ecosystem, processes such as birth, death, or migration, as well as the explicit match between individual age and the passage of time. Viewed through a lens that traces heritable lines of descent, mass and energy transformations are incidental consequences. Transformations of energy and material are the byproducts of life struggles whose object is indefinite persistence.

In 1961, G. E. Hutchinson coined the phrase “paradox of the plankton” to define the challenge to explanation presented by the species diversity of plankton communities. Nets towed from several hundred meters depth to the surface in the Pacific Ocean north of Hawaii, for example, routinely collect more than 300 species of zooplankton, and the richness of phytoplankton species in the surface waters is equally great. The oceanic pelagic region is the oldest continual habitat on the planet and its denizens are the product of ceaseless natural experiments. Near coastal regions and in lakes and rivers, the permanent plankton are joined by the larvae of benthic organisms. To Hutchinson, the con-temporaneous existence of so many distinct genetic lines in habitats that lack obvious structural complexity begged important questions about coexistence, interactions, competition, and resource use. Faced with a bewildering array of potential species interactions, investigations of the marine pelagic ecosystems have emphasized mass and energy flow rather than individual species dynamics. Compounding the problem of overwhelming diversity is the fact that marine plankton are notoriously difficult to census accurately, owing to the physical movements of water masses, to such an extent that some workers believe that time series data that are essential to population studies are nearly impossible to gather.

In an effort to span the breach between measurements of organic composition in units of carbon or nitrogen and the realities of the ways matter is packaged as individual organisms, there has been great interest in finding rules of general validity and broad predictive strength that blend the approaches. Special attention has been paid to relationships based on individual body size or biomass. These size-based or allometric models of ecosystem processes hold the promise of predicting metabolic rates and trophic interactions from simple measurements. Extensive tabulations have become available for physiological processes like respiration, motility, body growth, and feeding rates versus individual size. This activity has spurred the drive toward models of ecosystem dynamics that treat the size structure of organisms present in a system rather than the phylogenetic composition of the communities.

II. BIOLOGICAL COMPARISONS BETWEEN FRESHWATER AND MARINE ECOSYSTEMS

Freshwater ecosystems exhibit reduced species richness compared with marine systems. Many important invertebrate groups (e.g., Echinodermata, Ctenophora, Chaetognatha) have failed to colonize freshwater habitats, although in some cases their roles have been assumed by successful radiation of aquatic insects, particularly the Diptera, in lakes and streams. Much of the difference may be owed to the greater depth, antiquity, and continuity of oceanic plankton environments. The role of age alone is problematic, however. The great ancient lakes of the planet such as Baikal, Tanganyika, and Malawi, with basin ages measured in hundreds of thousands to a few millions of years, exhibit endemic species radiation of some groups but not all. The zo-
plankton faunas of the ancient lakes are notably undiversified, despite rich endemism among some fish, mollusks, or amphipods. Not only are there differences in overall species richness, but there are some differences in latitudinal trends as well. In general, the diversity of marine plankton is greater at low latitudes than at high latitudes. The latitudinal trend in species richness for freshwater plankton is the opposite. Tropical lakes have abbreviated zooplankton faunas compared with temperate sites. The tropical lakes are depauperate of large-bodied Cladocera and copepods, but they are poor in small-bodied pelagic rotifers as well.

III. PRIMARY PRODUCTION

A basic unit of measurement, and also a fundamental basis for comparisons among aquatic ecosystems, is the rate of primary biological production. Several methods are used, but they rely on the overall chemical reaction of carbon fixation in photosynthesis:

\[ 12 \text{H}_2\text{A} + 6 \text{CO}_2 \rightarrow \text{C}_6\text{H}_{12}\text{O}_6 + 12 \text{A} + 6 \text{H}_2\text{O} \quad (1) \]

where \( A \) represents an element that serves as electron donor for the photochemical oxidation-reduction reaction. In photoautotrophic reactions of algae and bacteria in lakes and oceans, oxygen, sulfur, or reduced organic compounds are used as the electron donors. Methods for measuring primary production differ depending on whether the focus is on the transformation of inorganic carbon into organic matter, the resulting release of oxidized product, or changes in the internal cellular redox system or photochemical state. The different methods are not equivalent, and the stoichiometry of carbon fixed to oxidation product released is not strictly 1 to 2 as indicated in Equation 1. Equation 1 is a simplification of the true synthetic reactions involved with cellular growth. Synthesis products are not only hexose sugars, but include all sorts of carbohydrates, as well as proteins, lipids, and nucleic acids. The photosynthetic quotient (PQ) of oxidized product released to carbon fixed varies according to the dominant synthesis products.

In practical application, measurement of primary production relies on one of two approaches. Either measurements are made on subsets of the natural community, which are enclosed and isolated for an experimental time duration, or the measurements are made directly on the natural community without isolation.

Both approaches have advantages and potential complications.

A. Oxygen-Based Methods

To avoid the complexity of diffusion or advection of dissolved substances and gases in or out of a water parcel, most measurements of primary production are conducted in enclosures. During the 1920s, oceanographers introduced one such method that is still in wide use: the light and dark bottle oxygen method. The method relies on making three measurements of oxygen concentration: (a) the initial concentration of dissolved oxygen in a water sample at the start of the experiment, (b) the final concentration of oxygen in a water sample that was enclosed in a transparent bottle called the Light bottle, and (c) the final concentration of oxygen in a water sample enclosed in an opaque bottle called the Dark bottle. From these three experimental measurements it is possible to deduce rates of respiration (\( R \)), gross primary production (GPP), and net primary production (NPP):

\[ R = \frac{([O_2]_{\text{light}} - [O_2]_{\text{dark}})}{\Delta t} \quad (2) \]
\[ \text{GPP} = \frac{([O_2]_{\text{light}} - [O_2]_{\text{dark}})}{\Delta t} \quad (3) \]
\[ \text{NPP} = \frac{([O_2]_{\text{light}} - [O_2]_{\text{dark}})}{\Delta t} \quad (4) \]

Where \( \Delta t \) is the duration of the incubation. The experimental bottles are either suspended at specified depths in the water column at the sampling site for duration of the experimental incubation, or they are placed in light and temperature conditions that simulate submersine conditions. The duration of experimental incubation \( \Delta t \) is invariably a compromise between the desire to obtain measurable changes in oxygen concentration and the desire to minimize artifacts resulting from prolonged exposure, such as growth of microorganisms on bottle surfaces or development of supersaturated oxygen concentrations inside the bottles. Typical incubation durations range from 4 to 24 hr.

B. Carbon-Based Methods

Methods that record fixation of inorganic carbon into organic matter rely either on measuring the removal of inorganic carbon or the appearance of new carbon in the organic matter. The pool of inorganic carbon available for photosynthesis in aqueous solution includes not only dissolved aqueous carbon dioxide, but also the reaction products of carbon dioxide with water molecules.
Carbon dioxide reacts with water to form carbonic acid:

$$\text{CO}_2 + \text{H}_2\text{O} = \text{H}_2\text{CO}_3$$  \hspace{1cm} (5)

Carbonic acid is a weak acid that dissociates to form its conjugate bases bicarbonate and carbonate:

$$\text{H}_2\text{CO}_3 = \text{HCO}_3^- + \text{H}^+$$  \hspace{1cm} (6)

$$\text{HCO}_3^- = \text{CO}_3^{2-} + \text{H}^+$$  \hspace{1cm} (7)

At equilibrium conditions the concentration ratio of carbon dioxide to carbonic acid is about 600 to 1. Proportions of carbon dioxide to bicarbonate to carbonate vary widely, but at the environmental pH of the ocean and many lakes, bicarbonate concentrations exceed all other molecular carbon species. The pool of dissolved inorganic carbon (DIC) available to photosynthesis is defined as

$$\text{DIC} = \text{CO}_2 + \text{HCO}_3^- + \text{CO}_3^{2-}$$  \hspace{1cm} (8)

The three dominant chemical species that comprise DIC exist in known stoichiometric relationships to each other as functions of pH, temperature, and ionic strength of the aqueous solution. There are several ways to measure or calculate DIC. An aqueous sample may be acidified, transforming all DIC to carbon dioxide, and the resulting gas can be measured. Alternatively, pH and CO$_2$ may be measured and then the other species are calculated. Or the concentrations of the conjugate bases can be measured by acid titration, and from their total plus measured pH, the DIC is calculated.

### C. C-14 Method

An alternative to measuring oxygen by light and dark bottle method is a method that uses radiocarbon as $^14$C-bicarbonate as a tracer. A small but known amount of radiocarbon is introduced to a water sample and the bottle is incubated for a time period in the same manner as with the oxygen method. At termination of the incubation period, the contents of the experimental bottles are filtered. Radiocarbon retained on the filters is considered to represent inorganic carbon fixed into particulate organic matter during the experiment. Any fixed carbon that leaked into the water from algal cells can also be assessed by acidifying the filtrate under vacuum to drive residual inorganic carbon out of solution. The radioactivity of residual organic release products can then be measured. The beta particles emitted from disintegrating C-14 nuclei are detected and counted by various methods, including gas or planchet Geiger-Muller (ionization) detector, liquid scintillation, or track autoradiography.

Calculation of total carbon fixation by the C-14 method requires knowledge of the specific activity of the inorganic carbon pool and of the isotopic fractionation differences between C-12 and C-14. Specific activity is the ratio of added radiisotope activity to the mass of stable isotope that the radiisotope is intended to trace. In this method the radiocarbon traces the pool of DIC. Uptake of inorganic carbon by photosynthetic organisms involves the kinetic process of diffusion and active transport across cell membranes. In such processes there are differences in the mobility of isotopes of the same element owing to differences in molecular mass. Empirical study has demonstrated that the ratio of C-12 uptake to C-14 uptake is approximately 1.06. Accordingly, the biological fixation of inorganic carbon is calculated as

$$\frac{\text{DIC fixed}}{\text{(total inorganic radiocarbon added})} = 1.06 \times \left(\frac{\text{DIC in the sample}}{\text{radiocarbon fixed}}\right)$$  \hspace{1cm} (9)

Both light and dark bottles are used in estimation of primary production by the C-14 method, but interpretation of results from the dark bottles are quite different from interpretations for the oxygen method. In the case of C-14, the dark bottle does not measure respiration, but rather it records the rate of nonphotosynthetic carboxylation reactions by algae and bacteria. In simultaneous comparisons between C-14 and oxygen methods, it appears that C-14 measures something intermediate between net and gross primary production. The reason for this is that some but not all of the carbon fixed during the experiment is preferentially respired during the incubation period.

### D. Fluorescence Methods

Indirect methods for assessing primary production rely on the fact that photosystem pigments alternate between a ground state in which they are able to absorb excitation photons of characteristic wavelengths and an energized state in which they either transfer the excitation energy to a chemical reaction or fluoresce a photon at longer wavelength and return to their ground state. The proportion of pigments in one state or the other varies with the rate of primary production expressed per unit mass of pigment. The usual reference
pigment is chlorophyll $a$, the antenna pigment present in all aerobic photoautotrophs. Application of indirect approaches requires calibration against direct measurements of primary production. Their attraction is their potential to estimate primary production in natural communities without isolation.

E. Interpretation and Analysis of Primary Production Results

Rates of primary production vary with depth according to light intensity, temperature, algal biomass, and physiological state of the algae. The photosynthetically active spectrum includes light from 400 to 700 nm. Near surface, light intensities are often sufficient to saturate the antenna pigments with photons. At high light, rates of photosynthesis are limited by the rates of biochemical dark reactions, specifically the carboxylation reactions, rather than by interception of light photons. Because carboxylation is enzyme dependent, the maximum rates of carbon fixation are temperature dependent and they vary with nutritional status as well.

Light intensities diminish with depth. At low light, the rate of primary production is limited by the rate at which photons are intercepted, and carbon fixation varies directly with light intensity. Temperature variations are less important at low light because in photochemical reactions limited by interception of photons, the role of temperature-dependent enzyme kinetics is minimized.

Respiration rates vary with temperature. Near the surface, as a daily average, gross primary production often exceeds respiration and net primary production is positive. At greater depth, however, gross primary production declines and a depth is reached at which net primary production equals zero. This depth is termed the compensation depth. For purposes of predicting the physiological state and growth response of the algae, it is important to recognize that organisms in aqueous suspension do not always maintain fixed vertical positions in the water. What is most important is the integral difference between the rates of gross primary production and of respiration during 24 hours:

$$ \int_0^{z_{mix}} \frac{\partial}{\partial t} \text{GPP}(z, t) - \text{R}(z, t) \, dz \, dt $$

where $z_{mix}$ is the maximum depth of water involved in vertical mixing during 24 hours. When the integral defined by Equation 10 is positive, net growth will occur. Seasonal variations in photoperiod, water transparency, temperature, and species composition influence the components of Equation 10, and so the critical mixing depth for net positive algal growth varies likewise.

IV. SECONDARY PRODUCTION

The principle of mass and energy balance used in primary production studies can be extended to heterotrophs. Among herbivores, predators, and detritivores, material and energy are considered commodities that continually turn over through biochemical means and by replacement of individuals within a population. Secondary production is the total growth increments over a given time interval as experienced by all individuals within a population that were alive at the beginning of the interval, whether or not they survive the complete interval. Unlike primary production, there is no distinction between gross and net production; secondary production ($P$) is inherently a net balance of several factors:

$$ P = I - E_g - E_x - R - M - G $$

where $I$ is ingestion, $E_g$ is egestion of unassimilated food, $E_x$ is excretion, $R$ is respiration, $M$ is molts or exuvia, and $G$ is gametes and reproductive products such as egg yolk and spermatophore capsules.

The efficiency of energy or material transfer during secondary production is expressed by several quotients. Assimilation efficiency is the ratio of assimilation ($I/E_g$) to ingestion ($I$). Net growth efficiency is the ratio of growth ($P$) to assimilation. Gross growth efficiency is the ratio of growth ($P$) to ingestion ($I$). Ecological efficiency is sometimes defined for predator-prey trophic interactions. Ecological efficiency is the ratio of predator production to prey production.

A. Bioenergetic Analysis

Bioenergetic analysis places its frame of reference on individual organisms of specified size, weight, or age. When Equation 11 is applied at the individual level, the result ($P$) is incremental growth. The units of accounting can be total body mass, content of carbon, nitrogen, or phosphorus, or calories. Analysis is facilitated if each of the terms on the right side of Equation 11 can be expressed with reference to body mass. For example, ingestion rate may be expressed as a function of food types and availability, temperature, and body mass of the consumer. Respiration may be expressed...
as a function of temperature, activity level, and body mass. In this way, the incremental growth of individual organisms is linked with organism size and a set of environmental conditions. The approach can then be extended to the population level by summing calculated growth increments across the empirical size distribution of the population.

**B. Biomass Accrual**

The standing stock biomass of a population is the sum of the weights of all individuals in the population. Changes in biomass occur owing to changes either in number \( (N) \), or mean weight \( (W) \):

\[
\Delta \text{ Biomass} = \Delta (N \times W) = N \Delta W + W \Delta N \tag{12}
\]

Equation 12 suggests a means to calculate secondary production for populations consisting of distinct cohorts. Presence of distinct cohorts is often the case among long-lived, seasonally reproducing populations. In such cases, a survivorship chart or life table for each cohort (decreasing \( N \) versus time) defines \( \Delta N \). A parallel chart or table reporting the average individual weights of cohort members versus age or time defines \( \Delta W \).

When cohorts cannot be distinguished, as happens with continually reproducing populations, secondary production can be calculated by summing the growth increments \( \Delta w_i \) of individual life history stages:

\[
P = N_1 \Delta w_i / T_i + N_1 \Delta w_j / T_j + N_i \Delta w_k / T_k + \ldots + N_i \Delta w_k / T_k
\]

where the subscripts denote individual stages (e.g., instars) or size classes and where \( T \) represents the mean duration of each stage. Abundance at each stage \( N_i \) is considered to be the mean stage-specific abundances during the period of interest.

**C. Birth and Death Rate Analysis**

Numerical changes in populations can be represented as a simple function of population size \( (N) \):

\[
\frac{dN}{dt} = r \times N \tag{14}
\]

where \( r \) is the net intrinsic population growth rate \( (\text{time}^{-1}) \) resulting from additions and removals:

\[
r = \text{birth} - \text{death} + \text{immigration} - \text{emigration} \tag{15}
\]

In cases where changes owing to migration are not an issue, net population growth amounts to the balance between birthrate \( (b) \) and death rate \( (d) \):

\[
r = b - d \tag{16}
\]

Over short time intervals an assumption is made that birth and death rates are stationary, so that the simple integral solution to Equation 14 is

\[
N(t + \Delta t) = N(t)e^{rt} \tag{17}
\]

and net intrinsic population growth rate \( r \) can be calculated from population sizes at the beginning of any time interval \( \Delta t \):

\[
r = \ln[N(t + \Delta t)/N(t)]/\Delta t \tag{18}
\]

To decompose the net rate \( r \) into its individual components, an independent estimate is needed for either birth or death rate.

**D. Egg Ratio Method**

The egg ratio method, pioneered by W. T. Edmondson, calculates birthrate from demographic properties of populations in nature. The method is particularly successful in application to parthenogenic populations, especially to species in which females produce and brood clutches of eggs, such as among rotifers and Cladocera.

The egg ratio, \( E \), is defined as the ratio of eggs and embryos to the sum of all postembryonic stages (juveniles and adults) in the population. From egg ratio and duration of development for the embryonic stage \( (D) \), the best estimate for population birthrate \( (b) \) is

\[
b = \ln(E + 1)/D \tag{19}
\]

Derivation of Equation 19 requires assumption of a stable age structure for the population, and further that all embryonic and postembryonic stages experience a common death rate \( (d) \), such that \( d \) can be calculated from \( r \) and \( b \) by difference:

\[
d = b - r \tag{20}
\]

These assumptions are most nearly applicable to short-lived species with abbreviated juvenile stages. Accuracy of the birthrate estimate is improved if the egg ratio is based on a census of egg stages that are in final phases of development and if the development time is corre-
spondingly restricted in range. Most of the populations to which this analysis is applied are ectotherms, so egg development times are strong reciprocal functions of water temperature.

E. Instar Analysis

For populations that exhibit distinct morphological stages, such as size classes or the developmental instars of arthropods, it is possible to estimate stage-specific mortality. This method requires knowledge of the durations ($T_i$) of each stage including their variation with time and water temperature. The numerical change in each stage is defined as

$$\frac{dN}{dt} = N_i \int_{T_i-1}^{T_iT_i} - \frac{dN}{dN}$$

(21)

The first term on the right side of Equation 21 represents recruitment of new individuals into the stage or age class from the preceding stage. The second term is recruitment out of the stage, and the third term is mortality within the stage. This approach assumes a uniform age distribution within each stage. It further assumes that the calculation time step is small compared to the stage durations $T_i$.

Instar analysis may be combined with birthrate estimation by the egg ratio method to estimate recruitment into the youngest instar category. Addition of mass or energy information about each instar or stage permits further calculation of secondary production according to Equation 13.

V. BIOGEOCHEMISTRY AND NUTRIENT CYCLING

Transformations of matter and energy in aquatic ecosystems are dependent on, and in turn influence, the availability of all the elemental constituents of protoplasm including both major components like carbon and nitrogen as well as trace constituents like iron and manganese. Even elements and compounds that are not essential constituents of biological material are affected by ecosystem processes. For example, redox reactions and pH changes caused by biological reactions can influence the solubility and reactivity of metals like mercury and cadmium, which can become toxic.

Alfred Redfield is credited with the conceptual theory of “biochemical circulation” within ocean ecosystems, and the theory is equally applicable to fresh waters. According to this view, processes of synthesis and decomposition may be separated in space and time, but they remain linked. Organic matter is generated at the ocean surface where radiant energy from sunlight permits positive net primary production. Carbon is assimilated from inorganic sources into organic form, together with nitrogen, phosphorus, silicon, iron, and all the other constituents of protoplasm. Over time, a portion of this synthesized organic matter will be transported actively or passively to deeper depths in perpetual darkness where photosynthesis is impossible. Once there, the allochthonous organic matter is used in secondary production, but its ultimate fate is to be recycled to inorganic mineral form or to be buried in sediments for long periods of geological time. Organic matter that is not transferred to the depths is recycled in situ, owing to the production inefficiencies of multiple secondary production pathways including herbivory, predation, and detritivory.

Physical processes of upwelling and thermohaline circulation permit some mineral nutrients dissolved in deep water to be returned to the surface for another round of synthesis reactions. Over geological time scales even the elements buried in the ocean sediments can become available again through weathering of the ancient deposits. This alternation between the inorganic state of an element and a state in which it is associated with organic processes at both biological and geological time scales is the basis for the term biogeochemistry.

For elements such as carbon and nitrogen, organic transformations entail changes in oxidation state and allied chemical properties. For others such as phosphorus and silicon, transformations affect not oxidation state but rather solubility.

Elemental nutrients that are essential for the production of organic matter can be traced through ecosystem transformations owing to the principle of conservation of matter. Quantitative illumination of the pathways has led to production of descriptive “cycles” for each element. Different aquatic ecosystems exhibit characteristic magnitudes of different pathways. Even water itself is involved in a hydrological cycle, in which water alternates among liquid, gas, and solid phases, and among ocean, atmosphere, and terrestrial environments. Water evaporates from the sea surface to the atmosphere, from where some of it falls as rain on the continents.

Surface and groundwater on the continents react with carbon dioxide from the air and from respiration of soil biota. The resulting solution thus includes carbonic acid. In some regions the carbonic acid is supplemented by strong acids introduced by anthropogenic activities. For example, combustion of fossil fuels introduces oxides of nitrogen and sulfur into the atmosphere, because
the elements were components of the ancient prote-
plasm that underwent diagenesis to form the fuel
sources. After reacting with atmospheric water vapor,
the oxides enter aqueous solution as nitric and sulfu-
ric acids. The resulting mix of weak and strong acid is the
primary agent of chemical weathering, a process that
dissolves the rocks of the continents. Chemical weather-
ing accounts for most of the ions in river water.

Elements that enter the ocean by runoff from the
continents or as wind-blown dust are subject to further
reactions and removal processes. Biological processes
are prominent among these. Microbiological processes
reduce sulfate to sulfur, followed by loss of hydrogen
sulfide gas or chemical precipitation of metal sulfides.
Inorganic carbon is transformed into particulate organic
matter or is precipitated from solution with calcium as
the skeletons of marine organisms. Silica is precipitated
likewise, as cell wall covering or skeletal material for a
variety of plants and animals.

Inputs of new material and removal processes are in
close balance, for the bulk chemical composition of the
ocean appears to be in steady state. The relationship
between material flux and pool sizes in biogeochemical
cycles is expressed through the concept of residence
time, defined as

\[
\text{Residence time (yr)} = \frac{\text{Amount of a given element in the ocean}}{\text{Rate of addition or removal per year}}
\]

Elements that exhibit great biological reactivity, such as
the nutrient elements N, P, and Si, have short residence
times and are usually present at low concentrations.
Elements with lower significance to biological reactions
like Na and Cl have long residence times, and corre-
spondingly account for most of the dissolved salt in
sea water.

### A. New and Regenerated Production

In the late 1960s, R. C. Dugdale and J. J. Goering intro-
duced a conceptual model of biological production in
the surface ocean euphotic zone. The model represented
the euphotic zone as a compartment or box with inputs
and outputs of nitrogen. The inputs were delivered
via upwelling, nitrogen-fixation of diazo-nitrogen, and
river runoff from the continents. Outputs were the sink-
ing material consisting of dead plankton and fecal pel-
lets. In addition to the inputs and outputs, they de-
scribed internal recycling processes within the euphotic
zone, through which nitrogen was regenerated by zoo-
 plankton and bacteria.

To maintain steady state, the outputs from the eu-
photic zone must equal the inputs, irrespective of the
magnitudes of regeneration. Dugdale and Goering rea-
sioned that primary biological production that was sus-
tained by the inputs, or “new” nitrogen, should be called
new production, and that the primary production sus-
tained by regenerated nitrogen should be called regener-
ated production. “New” nitrogen typically arrives in
the form of nitrate, a form that is thermodynamically
favored at the redox potential of surface sea water, and
is the form to which organic matter is decomposed
derunder aerobic conditions. “Regenerated” nitrogen is
typically ammonium, which is at the same reduced
oxidation state as the primary amino nitrogen that com-
prised proteins. Most aquatic animals are ammonotelic
in their excretion metabolism. Thus, the forms of nitro-
gen used to support primary production of organic mat-
ter are a clue to the processes that dominate production.

The concepts were further refined by R. W. Eppley
and B. J. Peterson into a modern ecosystem paradigm
of biological oceanography. New production is sus-
tained by imported nutrients. It is considered to be
equal to the sum of sinking flux of organic matter plus
transfers of organic matter to higher trophic levels,
which may be exported from the ecosystem by, for
example, fisheries yields. By empirical evidence, ecosys-
tems dominated by “new” production exhibit higher
primary production overall and are more capable of
sustaining exploitation such as harvest of fisheries
stocks. Ecosystems dominated by “regenerated” pro-
duction cannot endure prolonged exploitation of their
sustaining elements.

The concept of new production and its linkage with
export production has further implications for global
biogeochemical cycles and specifically for carbon diox-
ide levels in the global atmosphere. Organic matter that
is exported from the surface ocean to the deep sea
represents a sink for DIC from the surface ocean. Defi-
cuts of DIC are replenished in part by dissolution of
carbon dioxide from the atmosphere. As a consequence
of this linkage, the fraction of global oceanic primary
production that is new production represents an upper
limit to the amount of carbon that can be exported and
sequestered in the deep ocean.

Techniques for measuring the rates of nutrient re-
generation differ depending on whether the measure-
ments are conducted in trophogenic regions or in tro-
pholytic regions. In tropholytic regions, primary
production is minimal and thus regeneration can be
assessed by measuring the accumulation of mineral nu-
trients directly. In trophogenic regions, synthesis reac-
tions dominate over regeneration, and regenerated nu-
trients are quickly reassimilated. Techniques for measuring nutrient recycling under such conditions rely on assessment of uptake and regeneration simultaneously, such as by isotope dilution. In isotope dilution experiments, a deliberate tracer such as $^{15}$N-ammonium is introduced to a closed system in which $^{14}$N is the predominant natural isotope. Over time, the ratios of $^{15}$N to $^{14}$N in the ammonium pool become diluted as regenerated $^{14}$N-ammonium is added, even while uptake of both isotope forms proceeds.

VI. STABLE ISOTOPES

Stable isotopes of natural elements are ubiquitous. They have often been collected and used as deliberate tracers, such as in studies of new and regenerated production, but they can be measured and used at natural occurrence as well. Owing to the proportions in which different nuclear species survived the first instants of the universe, and the proportions that have been retained in the planetary composition of the Earth, many common elements exhibit more than one stable form. Hydrogen, carbon, nitrogen, oxygen, and sulfur, for example, all have two or more nuclear configurations that differ in numbers of neutrons and hence differ in atomic mass. Oxygen-16, O-17, and O-18 are stable (not radioactive), but they exist in different proportions in the environment. The different forms can be distinguished by mass spectrometry. The preferred form of analysis is by isotope ratio mass spectrometer, which compares the stable isotope ratios in a sample with ratios in a standard.

Measurement of stable isotope ratios in natural materials has been a technique used by geochemists for decades to help interpret complex processes. The relative proportions of the stable isotopes vary from one medium or substance to another. Mechanisms that can change the proportions of two stable isotopes of the same element are called fractionation processes. Fractionations result from differing mobilities and reactivities by the same chemical element owing to differences in atomic mass. Both kinetic and thermodynamic factors affect the magnitudes of fractionation. Five general rules apply:

1. Elements with high atomic mass generally exhibit smaller fractionation among their isotopes than do lightweight elements.
2. If multiple isotopes of an element exist, fractionation is greatest between isotopes that have the largest atomic mass difference.
3. In unidirectional reactions, the lighter isotope becomes enriched in the endpoint.
4. In reactions that reach equilibrium, the lighter isotope is enriched in the reactant compound or phase that has the weaker bond strength.
5. As temperature increases, fractionation decreases asymptotically to zero.

Changes in the fractionation ratios with temperature have been the basis for using stable isotopes in geochemical studies as "paleothermometers".

Atmosphere, terrestrial, and marine environments are heavily dominated by single isotope forms of common elements, and the alternate isotopes are usually very rare. For example, in the atmosphere, O-16, O-17, and O-18 co-occur in overall ratios by atoms as 1 : 0.0004 : 0.002. Similarly, C-12 and C-13 occur in atmospheric carbon dioxide in the mean ratio 1 : 0.011. Given such disparities of magnitude, isotope ratio differences between samples and standard are calculated in $\delta$ notation with units of parts per thousand, or per mil ($\delta$‰). For example,

$$\delta^{18}O = \left(\frac{^{18}O/^{16}O}_{\text{sample}}/^{18}O/^{16}O_{\text{standard}} - 1\right) \times 1000$$

Isotopes are useful in ecosystem studies because physical reactions and enzyme reactions cause reproducible discrimination between isotopes. Reaction differences lead to differences in the composition of biological material, skeletal products, and inorganic nutrient pools. Stable isotopes have been used to infer and trace the origins and pathways of materials in aquatic ecosystems. They are useful when different sources are isotopically unique and when the sources change in predictable ways. Successful applications require that the magnitudes of all isotope fractionations that result from physical, chemical, and biological processes be known.

Isotopes of carbon and nitrogen have been used to trace food-web relations in freshwater and marine environments. Phytoplankton discriminate against C-13 during photosynthetic carbon fixation, just as they discriminate against C-14. The magnitude for discrimination against C-13 is less than for C-14, or about $-20$ to $-30 \delta$‰ with respect to the source DIC. Organic matter that originates from terrestrial sources sometimes has very different carbon isotope ratios than material that is of aquatic origin. Terrestrial plants fractionate atmospheric CO$_2$ differentially during photosynthesis according to whether they use C3, C4, or CAM pathways for carbon fixation. Similarly, organic matter generated microbially from methane as a

...
substrate typically exhibits unique carbon isotope ratios. Stable isotopes may thus be used to identify chemosynthetic pathways as well as photosynthetic ones. Carbon isotopic ratios in animals resemble those of their diets within about 1/100. Slight enrichment of C-13 in an animal versus its diet is presumed to be caused by preferential loss of C-12 during respiration or by preferential assimilation of C-13 from the food. Synthesis of lipid rather than protein can also influence the isotope ratios because there are reported fractionation differences between biochemical constituents. As long as the isotope ratios in different potential food sources are well defined and consistently different, the relatively conservative levels of fractionation for carbon by trophic level can indicate whether an animal is eating its food from one source, another source, or a definable mixture of the two.

Nitrogen isotope ratios also reflect the composition of an animal’s diet, but the animal is usually enriched with N-15 by about +5/100 compared with its food. This increased retention of N-15 over N-14 seems to be favored by thermodynamic factors associated with transamination reactions, and by kinetic factors leading to preferential loss of N-14 as excreted ammonium and urea. Reproducible differences in Δ-15N with trophic level provide a diagnostic measure of relative trophic position among organisms that depend on the same primary source of organic matter. Carnivores are isotopically heavier than herbivores, which in turn are isotopically heavier than the algae; omnivores are isotopically intermediate between herbivores and carnivores. Interpretation of nitrogen isotope dynamics can be complicated by temporal and spatial variations in isotope fractionation and nutrient source materials. In laboratory experiments when nutrients are not limiting, isotope fractionations associated with assimilation of nitrate and of ammonium can be large. However, if a nutrient element becomes limiting such that all of it is consumed, there can be no isotopic fractionation. In nature, seasonal alternation between times of nutrient excess and nutrient limitation is common, with the result that isotope ratios can vary greatly in the source material and in the primary producers. Such variations provide useful information about nutrient dynamics, but simultaneously introduce complication to interpretations of trophic relations particularly for long lived organisms.

V. Measurement, Analysis, and Prediction of Ecosystem Functioning: Major Protocols and Obstacles

GLOSSARY

biodiversity Number and composition of genotypes, species, functional types, and/or landscape units present in a given system.

diversity Conceptual view of an assemblage of organisms and of physical and chemical components in their immediate environment, and the flow of materials and energy between them.

ecosystem functioning Flow of energy and materials through the arrangement of biotic and abiotic components of an ecosystem.

ecosystem stability Capacity of an ecosystem to persist in the same state. It has two components: Ecosystem resistance is the ability to stay in the same state in the face of perturbation. Ecosystem resilience is the ability to return to its former state following a perturbation.

resource dynamics Inputs, outputs, and internal cycling of key resources, such as carbon, water, and mineral nutrients, in an ecosystem.

trophic transfer The amount of biomass and/or energy which is transferred from the primary producers to the herbivore-based food chain rather than directly from plants to detritivores.

THIS ARTICLE DEALS WITH the functioning of terrestrial ecosystems with emphasis on primary producers and their relationship to biodiversity. Primary producers, in particular vascular plants, are the major sustainers of terrestrial life. They determine the amount of energy and materials available to terrestrial food webs. Biodiversity in this context involves not only the number and relative abundance of species (taxonomic diversity) but also the kind and relative abundance of traits they possess (functional diversity). These traits influence, and in turn are influenced by, major ecosystem processes. Ecosystem resource dynamics (carbon, nutrients, and water) and ecosystem stability in the face of disturbance (resistance and resilience) are discussed, including conceptual issues and major theoretical and methodological approaches to their study.

I. WHY MEASURE ECOSYSTEM FUNCTIONING?

Ecosystem functioning involves processes such as primary production, trophic transfer from plants to animals, nutrient cycling, water dynamics, and heat transfer. Traditionally, the term has referred to functioning
in equilibrium, namely, the amount (how much), the rate (how fast), and sometimes the seasonal variations of those processes. Some authors believe that the responses of ecosystem processes to perturbation, resilience and resistance, should also be incorporated into the term. This is the approach taken in this article (Fig. 1). Ecosystem processes provide essential goods and services to humankind, such as food; fiber; fodder; fuel; water provision, control, and detoxification; amelioration of weather; soil formation; retention of carbon that otherwise would be released into the atmosphere contributing to climate change; and medicinal, recreational, and cultural resources. The impact of changes in the quantity and quality of services provided by various terrestrial ecosystems to humankind has been gaining increased attention, and in some cases their costs are very high compared with their traditional market value. The measurement of how much seed, green biomass, and animal biomass an ecosystem can produce or how much water and nutrients can be retained in situ are key inputs for an evaluation of ecosystem services to humankind. Concepts, methods, and data retrieval on ecosystem functioning have progressed enormously in the past few decades, and today an impressive body of quantitative information on flows and stocks of materials and energy through a wide spectrum of ecosystems is available. Much less is known, however, of the effects of perturbations on these processes. Physiological processes underlying biomass production, water balance, and nutrient cycling are well understood. However, there are still many theoretical and methodological difficulties and information gaps in the prediction of processes at coarser scales of time (decades or centuries) and space (ecosystems, landscapes, and biomes). In order to determine how the biosphere will respond to the changes in climate, atmospheric composition, and land use projected for the future, accurate predictions at these levels are vital.

**FIGURE 1** Conceptual diagram of the relationships between ecosystem functioning, biodiversity, ecosystem services, and external structuring factors. Rectangular boxes and solid arrows represent the main focus of this article (partially based on Chapin et al., 1998).
II. ECOSYSTEM RESOURCE DYNAMICS

Three main processes will be analyzed here, which are linked to the acquisition and loss of chief resources for terrestrial ecosystems: light, carbon, water, and mineral nutrients. These processes are biomass production (primary productivity and trophic transfer), nutrients (especially nitrogen) cycling, and water dynamics. There is a strong association between water flow, carbon assimilation, and nutrient uptake by a plant. Since carbon dioxide (CO₂) input and water output occur through open stomata, and nutrient and water uptake occur through root hairs and fine roots, they are usually linked. Nutrient availability controls the increase in plant mass, and incorporation of mineral nutrients into biomass is not possible without carbon assimilation. The derived processes at the ecosystem level, namely, biomass production, water balance, and nutrient cycling, are therefore closely linked and basically regulated by net radiation, temperature and precipitation, soil composition and structure, and the plants that are present. Any consideration of carbon, nutrient, or water balance in isolation is probably artificial. The examples presented here are described in different sections for the sake of clarity, but they highlight the strong interdependence of these processes.

A. Approaches to Analysis and Measurement of Ecosystem Functioning

1. Whole-Ecosystem Approaches and Approaches Based on Community Structure and Composition

The measurement of ecosystem functioning focuses on the sizes of major pools of resources, such as water, carbon, and mineral nutrients, and on the rates of flows connecting them. The emphasis on one of these two aspects has varied with time and authors. Not until the 1970s did compartmental models become an important tool in “systems ecology” (illustrations of this view can be found in the classic textbook on ecology by E. P. Odum, 1971). In these models, boxes represent pools or stocks (usually major trophic levels), and arrows signify the flows between them. This represents a first and very useful approximation. However, pools are often treated as “black boxes” in which only the general size, and not the internal composition, is important. This often makes this approach too coarse for the management of real situations and of very little predictive value for novel situations. In most cases, the whole pool is not altered, but instead subtle intrapool changes occur until a threshold is reached or substances are chemically altered or sequestered. This is because organisms which are members of the same pool tend to respond in an individualistic way and have slightly different properties. As a consequence, other approaches have focused on the internal composition of pools (what taxa or functional types are present within the boxes and in what abundance) and how changes in that composition can alter flow rates between pools. These approaches are strongly based on community structure and composition and will be addressed in Section IV.

2. Measurement of Short-Term Resource Dynamics and Long-Term, Large-Scale Ecosystem Processes

Some methods of ecosystem analysis emphasize the measurement of short-term process rates (e.g., photosynthesis, nutrient uptake, and evapotranspiration), whereas others emphasize the measurement of the size of pools accumulated as a result of these processes, with or without consideration of their internal components (e.g., biomass production, nitrogen stocks in different compartments, and water use efficiency integrated over a whole season) (Table I). The choice depends mostly on the objectives pursued and on the scale of observation selected. However, as a general rule, methods based on short-term flows provide more mechanistic understanding, but they do not provide a clear picture of what happens at the time and space scales most relevant to ecosystem functioning (meters to thousands of kilometers and months to decades or centuries). Measurements of flow rates (see measurements in Table I) tend to be very precise but highly variable. They give a snapshot of ecosystem functioning, but they do not necessarily reflect processes over a growing season. For example, short-term (hourly or daily) variation in gas exchange per leaf area is not directly reflected in annual biomass production. Plant growth and vegetation productivity cannot be directly equated with leaf photosynthetic rates. The productivity of plant communities is determined more by the amount of photosynthetic tissue (which is in turn controlled by carbon allocation) than by photosynthetic rate. There is often only a slight relationship between these two parameters. Gas exchange measures the instantaneous plant performance, whereas growth necessarily integrates along time and reflects plant allocation patterns. At the community level, additional regulations occur; therefore, caution is necessary in generalizing the ecological meaning of leaf physiological processes for production. For example, a 10- to 50-fold difference between species in maximum rates of photosynthesis at the leaf level is reduced

* More details can be found in Pearcy et al. (1989).

to only a factor of two to four at the primary production level between different forest types.

Therefore, for integral ecosystem responses, methods which focus on changes of pools (P measurements in Table I) are usually more meaningful and/or convenient. This point is illustrated by Fig. 2 and by some examples of the use of different methods for assessing biomass production at different scales (see Section II.B). An example is provided in Fig. 3. A long-term study of the responses of tundra-dominant plants to different treatments showed that processes that are readily integrated at annual time steps (shoot growth, mortality, and allocation) were more useful than instantaneous physiological measurements in predicting decadal vegetation changes. Strong treatment effects on photosynthetic rate (Fig. 3a) and nutrient uptake were poorly related to longer term changes in production and nutrient concentration (Figs. 3b and 3c). This was probably due to the operation of buffering mechanisms (e.g., allocation, nutrient relations, altered phenology, interspecific interactions, and positive and negative feedback mechanisms) which compensate for immediate physiological responses to the environment.

B. Biomass Production

Net primary production (NPP) is strictly defined as the difference between the energy fixed by autotrophs and their respiration, and it is most commonly equated to increments in biomass per unit of land surface and time. Because the increment in biomass over a given time depends on the rate at which new biomass is produced and also on the initial amount of carbon-assimilating photosynthetic tissue, stands with a large standing biomass often show higher NPP than stands with lower biomass. Therefore, another useful concept is that of relative productivity rate, or the time needed by a vegetation stand to produce its standing biomass. For example, the estimated relative productivity rate for a dry tropical forest can be many years, whereas in an annual grassland it is less than 1 year.

The fate of assimilated carbon—that is, whether it is allocated to increase the pools of aboveground or belowground biomass, root exudates, litter, soil organic matter, grazers, symbionts, or parasites—varies strongly between ecosystems, depending on prevailing climatic conditions, disturbance regimes, and allocation patterns of dominant plant functional types (Fig. 4).

At the regional scale, net primary production can be largely accounted for by climatic factors. For example, precipitation, potential evapotranspiration, and radiation are enough to account for the aboveground net primary production (ANPP) of North American forests, deserts, and grasslands. In regions of the United States with up to 1400 mm of annual rainfall, annual precipita-
tion is enough to account for 90% of the variability in ANPP of grasslands (Fig. 5a). At higher precipitation, ANPP depends more on other factors, and equations based on annual rainfall lose part of their predictive power. At the site level, variability in production seems to be accounted for by annual precipitation and soil water-holding capacity (whc; Fig. 5b). Soil whc can have a positive or negative effect depending on the precipitation value. In dry regions, major losses of soil water occur via bare soil evaporation. However, where sandy soils occur, bare soil evaporation is lower than in loamy soils because water penetrates deeper into the soil. For the same reason, surface runoff is also lower in sandy soils than in loamy soils. In more humid regions, substantial water losses occur via deep percolation, which is reduced in soils with high whc. This is known as the inverse texture hypothesis, proposed by I. Noy-Meir in 1973.

At finer scales of analysis (e.g., paddocks and vegetation patches), more variables are needed to account for ANPP. Species composition and land-use regime become important factors, although drivers at a coarser scale are still in operation and constrain responses (e.g., irrespective of management or species composition, annual precipitation will set an upper boundary to ANPP). For instance, in Argentine montane and pampean natural grasslands, ANPP decreased between 50% and more than 300% when subjected to moderate to heavy grazing. Species composition is crucial at this level; for example, ANPP tends to be higher in legume-dominated pastures than in grass-dominated ones because legume growth is much less limited by soil nitrogen availability due to their capacity for symbiotic nitrogen fixing.

Biomass production from local to global scales can also be estimated by remote sensing. The normalized difference vegetation index, derived from the reflectance in the red and infrared bands measured by the meteorological satellites NOAA/AVHRR (National Oceanic and Atmospheric Administration/Advanced Very High Resolution Radiometer), shows strong correlation with vegetation processes such as photosynthesis and primary productivity and has been widely used to assess primary production (Fig. 6).

C. Trophic Transfer

Trophic transfer can be defined as the amount of biomass and/or energy which is transferred from the primary producers to the herbivore-based food chain rather than directly from plants to detritivores. In this article, only the transfer from plants to herbivores will be analyzed. Two concepts are relevant: consumption,
or the amount of plant biomass consumed by herbivores, and net secondary productivity (NSP), or the amount of biomass/energy at the herbivore level which is available to carnivores. Both depend on the amount of available ANPP, the quality of plant biomass, the kind of metabolism of the herbivores, and the linkages between herbivores and plants.

1. Effects of Nutrient Availability, Plant Production, and Plant Quality on Herbivore Performance

Plant nutrient quality can directly affect animal populations. Plants growing in low-nutrient sites tend to have elevated concentrations of carbon-based secondary compounds that deter consumption by making a higher proportion of plant biomass unavailable. In addition, low foliar concentrations of nutrients can result in either decreased or increased consumption by herbivores. In the second case, herbivores (most commonly insects) consume higher quantities of biomass in order to meet nutritional requirements, with or without reduced fitness as the final result. This effect, sometimes called the “nutrient dilution effect”, is particularly true in the case of generalist herbivores, whose opportunities for co-evolutionary adjustment to the chemistry of a particular plant species are slight.
Secondary chemicals in foliage seem to be more important as regulators of the types of herbivores prevailing in different ecosystems and their dietary habits, than as regulators of consumption at the ecosystem level. There is evidence that herbivore biomass, consumption, and productivity are closely correlated with plant productivity across a wide range of ecosystems, such as deserts, savannas, agricultural grasslands, tropical forests, and salt marshes (Fig. 7). Respiratory costs per unit production at the consumer trophic level are higher for homeotherms (such as ungulates) than for heterotherms (such as insects). In forests, in which most herbivores are heterotherms, most production is allocated to wood, whereas in grasslands, in which homeotherms predominate, much higher production is allocated to green tissue. This explains why net foliage productivity predicts consumption considerably better than net aboveground biomass.

Herbivore biomass and consumption increase as a power of net aboveground primary production, whereas net secondary production increases linearly (Fig. 7). This indicates that highly productive ecosystems sustain a larger level of herbivory per unit of net aboveground primary production than unproductive systems. This larger level of herbivory, however, is accompanied by a lower secondary production per unit of consumption. Because the foliage unconsumed by herbivores will flow into decomposer food webs, the relationship shown in Fig. 7 between consumption by herbivores and net aboveground primary production indicates that the relative importance of the direct flow to detritus decreases as ecosystem productivity increases. However, the relative amount of litter which is actually consumed is small, even in the most productive systems.
2. Effects of Herbivores on Nutrient Cycling and Primary Productivity

Animal activity can affect nutrient cycling directly and indirectly. The amount of ANPP consumed by herbivores can vary from less than 10% in tropical rain forests to more than 50% in meadows (Larcher, 1993). Herbivores can short-circuit the decomposer pathway since urine and feces are much easier to decompose than plant litter. They can also redistribute nutrients and create patches (ungulates, rodents, and ants), and they can promote secondary compound production in plants, which may further deter grazers and may retard decomposition. Mammals, ants, and termites can play important roles in spatial distribution of nutrients at different scales, with impacts on the dynamics of the whole food web.

In many systems primary productivity increases with light grazing, then decreases, and finally decreases more or less sharply as grazing becomes severe. This was at the heart of the herbivore optimization curve hypothesis proposed by S. J. McNaughton in the 1970s. Herbivore optimization models are still under debate, and to determine whether total (aboveground and belowground) biomass actually increases under herbivory is operationally very difficult. However, supporting evidence has been found in a wide range of terrestrial ecosystems, including not only grasslands and wild and domestic ungulates but also forbs and geese, trees and mosses, and crops and birds. It is generally accepted that the highest production rates of plants occur when grazing occurs but it is not too high.

3. Bottom-up and Top-down Controls of Food Chains

Bottom-up or resource control in food chains emphasizes the importance of resource availability for primary producers and the subsequent energy and nutrient flow through a series of trophic levels. Organisms at each trophic level are food limited. The rationale of the opposite, or top-down, view is that organisms at the top of the food chain are food limited but those at lower trophic levels are alternatively predator and food limited. Both mechanisms are recognized to occur in nature, with their importance varying from place to place. S. D. Fretwell and L. Oksanen proposed that the importance of top-down control increases with primary productivity. This idea has recently been empirically demonstrated for invertebrate herbivory and predation on limestone grasslands through a series of experiments summarized in Fig. 8 involving pesticide treatments, transplant of turves, and the use of bioassays (lettuce discs and blowfly maggots in order to evaluate the degree of herbivory and predation, respectively).

D. Nutrient Cycling

1. Nutrient Capture, Retention, and Release by Plants

A key, albeit controversial, concept in relation to nutrient cycling is that of resource use efficiency, or the
relationship between a limiting resource (light, nitrogen, and water) and a biological process (photosynthesis and primary production). Nutrient use efficiency was originally defined in the early 1980s by P. Vitousek as the total NPP (above- plus belowground) per unit nutrient absorbed annually. In practice, it has been usually measured as the ratio of dry mass to nutrient content in litter (Table I), which is a good index of the nutrient economy in a stand as a whole and is based on information reasonably easy to obtain. Recently, a distinction has been proposed by J. Pastor and S. D. Bridgham between nutrient use efficiency (production per unit nutrient uptake) and nutrient response efficiency (production per unit nutrient available).

2. Major Controls over Nutrient Cycling
The main factors underlying variations in nutrient cycling in different ecosystems are climatic factors, soil
FIGURE 8 (a) Estimation of herbivore and carnivore activity, measured as a percentage of lettuce discs and maggots consumed, respectively, and (b) illustration of Fretwell–Oksanen theory of interaction between trophic dynamics and primary productivity in British limestone grasslands with low (I), intermediate (II), and high (III) productivity. At very low productivity, the vegetation did not experience a detectable amount of herbivory. Vegetation of intermediate productivity supported a high level of herbivory and responded strongly to the removal of herbivores. Productivity in this situation is believed to be insufficient to sustain a high intensity of "top-down" control. In the case of highly productive vegetation, carnivory was strong and the intensity of the top-down control by carnivores on plant mass removal by herbivores was maximum (reproduced with permission from Fraser and Grime, 1997).

3. Open vs Tight Nutrient Cycles
A concept strongly linked with nutrient use is the degree of "tightness" or "openness" of nutrient cycling in different ecosystems. This refers to the relative importance of within-system nutrient cycling vs external inputs and outputs. Tropical forests are considered systems with tighter nutrient cycling than temperate forests because within-system nutrient recycling is more important than influx into or effluxes out of the system.

4. The Effects of Rainfall
Concentrations of available nutrients in the soil are relatively (although not absolutely) high in semiarid sites and decrease with increasing precipitation. Soil organic carbon tends to follow the opposite pattern, increasing with increasing rainfall. While total soil nutrient content may also increase, carbon: nutrient ratios in soil increase with higher mean annual precipitation. This suggests that, as rainfall increases, rate of carbon accumulation in soils is higher than that of total nutrient accumulation due to differences in mineralization.

Changes in nutrient cycling "tightness" with climatic factors are well illustrated by an analysis of soil and foliar nutrients in a rainfall gradient in Hawaii (Fig. 9). As rainfall increases with altitude, there is a shift from relatively high nutrient availability to relatively high carbon gain by producers, indicated by a decrease of leaf mass and leaf nitrogen concentration and an increase in lignin concentration with altitude (Fig. 9b). A progressively depleted 15N signature in both soils and vegetation in the wetter sites (Fig. 9a) suggests that N cycling shifts from more open at the drier sites (larger turnover) to tighter (smaller losses) as precipitation increases.

5. The Effects of Soil Type, Land Use, and Vegetation Structure
A comparison among different types of Amazonian rain forest ecosystem, differing in soil properties and topographic positions (Table II), illustrates how patterns of nutrient allocation depend on soil chemical properties and flooding regimes. In turn, soil properties influence nutrient supply, and flooding regimes affect nutrient uptake ability. Mixed and guaço forests, located in higher topographical positions, show relatively high nitrogen contents in both soil and vegetation. In the tall caatinga forest, the proportion of total nitrogen in living biomass is much higher than in the mixed forest...

and guaco forests, and decomposition is slower, associated with waterlogging and nitrogen limitation. Nitrogen circulates in larger amounts in mixed and guaco forest, which show more "open" nitrogen cycling than tall caatinga forest.

Changes in vegetation structure due to land use can lead to different nutrient relations in sites under similar climatic and original soil conditions. A comparison between a tropical dry deciduous forest and savannas derived from the same forest and now maintained by grazing and fire in northern India (Table III) shows that nutrient cycling is faster in the vegetation, litter, and soil of the savanna. The forest shows a higher nutrient use efficiency: Whereas the biomass and nutrient content are much higher, the annual net production and nutrient uptake are similar to those of the savanna. In the savanna there is smaller permanent nutrient storage, and significant nutrient leakage from the system, reflected in lower soil content, indicating more open nutrient cycling.

E. Decomposition: From Nutrient Organic to Inorganic Forms Available to Plants

The process of decomposition, or disintegration of plant and animal residues by the soil detrital food web, is a
key step in nutrient cycling since it makes nutrients already present in the system available for new plant growth. Some plants can incorporate organic forms of nitrogen with or without the intervention of mycorrhizal symbionts. However, these cases seem mostly restricted to very nutrient-poor systems. In most ecosystems, the majority of primary production is not consumed by herbivores but passes directly to detritus. A smaller fraction of primary production is incorporated into herbivores and carnivores which becomes detritus when these organisms die. The ultimate end product of organic matter breakdown is inorganic forms of carbon (CO$_2$) and nutrients (nitrates, ammonium, and phosphates). Decomposition depends on soil environment (water potential, temperature, and aeration), microsite characteristics (slope, texture, drainage, aspect, and cover type), substrate quality, and composition of decomposer community (size and specific composition of animal and microbe assemblages and synergistic or antagonistic relationships among them).

The control of decomposition by macroclimatic parameters is very strong. Whereas mean NPP increases by a factor of approximately 20 from tundra to tropical rain forests, mean residence times of dead organic mat-

ter decrease by a factor of approximately 200 primarily because soil temperatures limit decomposition more than air temperatures limit production.

At a more local scale, litter quality plays an extremely important role in determining decomposition rates. The relative velocity of decomposition of litter from different plant species tends to remain constant under different environmental conditions and to be strongly correlated with the palatability of living leaves. This suggests that the same compounds which determine palatability aboveground control litter decomposition by soil microbiota. The most widely used indexes to describe litter quality are the carbon : nitrogen and lignin : nitrogen ratios, with higher ratios being associated with lower decomposition rates (Table IV).

2. Litter Decomposition and Composition of Detrital Food Webs

The composition of the decomposer communities, which include macrofauna (earthworms and arthropods that carry out initial comminution, mixing, and dispersion of litter and microbial propagules), mesofauna (springtails, mites, and enchytraeid worms), and microbiota (fungi, bacteria, protozoa, nematodes, and actinomycetes), also determines the local decomposition rate. Grazing on the bacteria, actinomycetes, and fungi is important (often indispensable) for net mineralization to occur. Several experiments manipulating densities of bacteria, fungi, and their predators (e.g., protozoa and nematodes) and macrofauna (e.g., millipedes) have shown that the composition of the detrital food web is a strong factor determining the balance between net mineralization and immobilization. Belowground grazing on bacteria and fungi and aboveground grazing on plants have both been shown to increase microbial activity and mineralization.

### F. Water Dynamics

Water flow through the plant compartment of the soil–plant–atmosphere continuum is regulated at the plant–air interface, where the transition of liquid water to vapor occurs and the steepest gradient of water potential exists. At this interface, the shoots are exposed to the low water potential of the air and a flow of water through the plant is set in motion. In this way, and depending on xylem structure and cavitation, the plant component of the system bridges the steep water potential gradient between soil and air.

Vapor loss from land and surfaces is governed by leaf area, by stomatal and aerodynamic conductances of plant canopies, and by the contribution of evaporation from soils, and it affects numerous terrestrial processes ranging from the biogeochemical cycling of elements to the development of regional climate. The
ECOSYSTEM FUNCTION MEASUREMENT, TERRESTRIAL COMMUNITIES

III. ECOSYSTEM FUNCTIONING UNDER DISTURBANCE: RESISTANCE AND RESILIENCE

Ecosystem stability is often divided into two components: resistance and resilience. Ecosystem resistance is the ability of a system to avoid change—the capacity to stay in the same state in the face of perturbation (e.g., fire, unusual frost or drought, plowing, eutrophication, and pollutant input). Ecosystem resilience is the rate at which a system returns to its former state after being displaced from it by a perturbation. Not all aspects of ecosystem functioning are equally resistant or resilient. The most commonly measured ones (which are not necessarily the most important or sensitive ones) are species composition and biomass. Usually, a standard or ad hoc index is constructed that relates vegetation structure or composition before the perturbation to that after the perturbation. A higher dissimilarity means the ecosystem has a lower resistance. The longer amount of time needed to achieve maximum similarity between the predisturbance and postdisturbance situation, the lower the resilience. Some authors have used indicators other than community composition, such as nutrient loss rate, to estimate stability; the higher the relative nutrient loss rate following disturbance, the lower the resilience. Evidence has accumulated for the idea that both components of ecosystem stability are primarily determined by key traits of the dominant plant species. Highly productive communities, dominated by fast-growing plants, tend to have high resilience and low resistance, with the opposite being true for communities dominated by slow-growing plants. Productivity and seed production (especially persistent seeds) favor resilience, whereas preferential allocation to storage and...
defense favors resistance. These ideas were formalized in the early 1980s on the basis of studies of old-field successional communities (Fig. 11). Recently, new experimental support has been provided for the idea that vegetation resistance and resilience in the face of extreme events are a function of the nutrient stress tolerance of the component species. Figure 12 clearly illustrates that resistance to extreme events increases, and resilience decreases, with increasing nutrient stress tolerance in herbaceous communities.

FIGURE 11 Relationship between life history strategies of dominant plants and community resistance and resilience (reproduced with permission from Kluwer Academic Publishers, Lepp et al., Fig. 5 © 1982 with kind permission from Kluwer Academic Publishers.).
ECOSYSTEM FUNCTION MEASUREMENT, TERRESTRIAL COMMUNITIES

The size and the turnover rate of the detrital compartment also have implications for ecosystem stability. Ecosystems with high carbon:nutrient ratios in the soil are effective at immobilizing large amounts of nutrients.

This immobilization can substantially control the nutrient losses as long as a sufficient amount of plant residue is left on the site to sustain the microorganisms that immobilize the nutrients in their biomass. Therefore, soil organic mass is a major determinant of ecosystem resistance. On the other hand, systems with tight nutrient cycles have increased return time to equilibrium (lower resilience). When substantial amounts of biomass are removed from these systems, causing high nutrient loss, recovery may be very slow because there is little throughflow of nutrients coming from outside the system compared with the nutrient lost. As a general rule, higher nutrient mean residence time in an ecosystem increases its resistance and decreases its resilience.

IV. ECOSYSTEM FUNCTIONING AND FUNCTIONAL DIVERSITY

A. Taxonomic and Functional Diversity

The most common way of assessing biodiversity is the measurement of the number and relative abundance of species per area. Taxonomic diversity per se is an important parameter for conservation, but it provides little information on the magnitude and rate of ecosystem processes. On the other hand, as discussed in Section II,A, measurements of pools and flow rates at the whole ecosystem level provide little information about a system’s conservation value or about its likely response in the face of a perturbation. An intermediate approach is the one based on plant functional types. Functional types are sets of plants sharing similar responses to environmental conditions and similar effects on major ecosystem processes. This approach is as old as ecology itself, but it has gained renewed interest in the past few years because it bridges the gap between individual species and whole-ecosystem functioning, explains particular values of pools and flow rates, and improves predictions of how ecosystems can be modified by the introduction of new abiotic (e.g., fertilization) or biotic factors (e.g., invasion by alien species).

The practical value of distinguishing discrete “types” is obvious. However, it is important to bear in mind that many real plants represent transitions between, rather than typical examples of, different functional types.

B. Ecosystem Functioning and Biodiversity

Although the role of species richness per se remains controversial, and the evidence is sparse, the impor-
FIGURE 13 Proposed ecosystem effects of species in different positions along an idealized dominance–diversity curve. Transients are those species unable to regenerate and persist in situ; their sources are soil seed bank and seed rain from the surrounding landscape. Immediate effect, control over major processes of resource dynamics; filter effect, positive or negative influence on the regeneration of dominants following major perturbations; founder effect, reservoir of potential colonizing dominant and subordinate species in the event of ecosystem reassembly (adapted from Grime, 1998 with permission from Blackwell Science Ltd.).

C. Links between Plant Functional Traits and Ecosystem Functioning

The existence of suites of vegetative traits consistently associated across taxa and ecosystems (e.g., plants that "go for it" and plants that "sit and wait") has been repeatedly documented and is increasingly accepted. Central to the plant functional type approach is the idea that life history, allocation, and phenological, physiological, architectural, and reproductive traits of dominant plant species appear to be associated in a limited number of combinations and strongly determine vegetation structure and ecosystem functioning (Fig. 14). By being primary components of ecosystem-level fluxes of matter and energy, dominant plant functional types are indirect determinants of the biogeochemical cycles of carbon, water, and nutrients. Individual examples of strong links between plant traits and ecosystem processes have accumulated in the past few decades (Table V).

Major ecosystem processes appear more strongly and directly linked to recurrent suites of vegetative traits than to regeneration traits (Fig. 14). Plant regeneration traits appear to be under the control of selective forces different from those that operate on resource dynamics during the established phase. In situ plant regeneration by seed is an important aspect of resilience and also strongly influences migration across the landscape in the face of climatic changes. Seed production, germination, dispersion, and establishment are therefore key aspects in determining ecosystem functioning in the face of major changes of climate and land use, although their role has proved much more difficult to document than that of adults-phase traits.

D. Positive-Feedback Switches

The effect of the biotic component on ecosystem dynamics often takes the form of "switches" or positive-feedback processes in which members of a community
modify their environment, making it more suitable for themselves. This term was coined in 1992 by J. B. Wilson and A. D. Q. Agnew, who provided an extensive list of examples, some of which are shown in Fig. 15.

V. MEASUREMENT, ANALYSIS, AND PREDICTION OF ECOSYSTEM FUNCTIONING: MAJOR PROTOCOLS AND OBSTACLES

A. Monitoring, Field Manipulations, and Synthesized Ecosystems: A Gradient of Questions and Methods

The understanding of how ecosystems function can be achieved by a whole gradient of protocols, from simply documenting what is happening in real systems to synthesizing model ecosystems from scratch. These extreme approaches represent a trade-off between realism and precision and between the documentation of general patterns and that of the specific mechanisms underlying them. The monitoring of real ecosystems often needs to be performed by “soft” approaches. It is important at the initial heuristic stage and when testing whether results found in simpler experiments can be reasonably applied to the real world (synthesis stage). Experiments on synthesized ecosystems, on the other hand, are ideal for the stage of testing specific hypotheses on mechanisms which may account for the patterns observed (analytic stage). Field manipulations lay in the middle of this gradient (Fig. 16).

1. Monitoring Real Ecosystems: Approaches Based on Hard and Soft Traits

Processes in natural ecosystems can be recorded by applying the usual methods (hard approaches) of measuring pools and flows described previously (see Sec-

* Modified from Díaz et al. (1999).

The presence of root symbionts (A.1 and A.2). They are sometimes termed hard approaches because they are quantitative and usually represent a direct measurement of a process. Alternatively, ecosystem functioning can be inferred from the presence and abundance of plant traits which are easily measured but at the same time have clear implications at the ecosystem level. These are called soft traits because they are usually indirect indicators of ecosystem processes. Some examples of soft traits are given in Table V. The soft approaches have the advantage that they need a minimum investment in financial and technological resources and can be utilized to characterize extensive areas or high numbers of systems in a short period of time. The result is usually a comparative estimation of ecosystem functioning (Fig. 17), which then needs to be calibrated against a hard approach. This is achieved by testing how well the soft traits correlate with hard traits, which have more direct and well-documented relationships with ecosystem processes (e.g., the soft trait leaf tensile strength correlates well with the hard trait decomposition rate, and the soft traits seed mass and shape correlate well with the hard trait seed persistence in the soil; Fig. 18).

2. Experimental Manipulations Involving “Natural” vs Synthesized Ecosystems

The major disadvantage of field experiments is that the degree of control of independent and external variables is low compared to manipulating them. The amount of “noise” (unwanted variance) is usually high, and enough replicates in order to reduce it are usually unavailable or involve prohibitive costs. On the other hand, synthesized ecosystems, such as microcosms, never come close to the realism of experiments involving manipulations of real ecosystems, they are always a badly simplified version of nature, and they have severe size limitations (e.g., for ecosystems based on woody vegetation). Considering the realism-precision trade-off illustrated in Fig. 16, and taking into account

FIGURE 16 General characteristics of different approaches to the study of ecosystems.
that some processes scale up poorly from single systems to complex ecosystems (see Section II,A,2); field experiments are indispensable. However, microcosms work has produced highly relevant insights into ecosystem functioning, including relationships between trophic levels, community roles of symbionts, feedbacks involved in soil fertility and climate manipulation, and some of the most controversial and inspiring experiments on the role of biodiversity in determining ecosystem functioning. Field manipulations, such as the application of treatments to real vegetation plots, or the selective removal of certain components of the community have some limitations. These include the difficulty of separating the effects of removal of one component from the effect of the disturbance caused during the removal process and the difficulty of minimizing spatial heterogeneity that usually masks treatment effects. However, they are an excellent intermediate step between laboratory experiments and the long-term monitoring of undisturbed systems. Additionally, they have produced important evidence of the difficulties and potentialities of scaling up from individual physiology to
ecosystem functioning (see Fig. 3), and they are likely to continue to provide fruitful insight in ecosystem ecology.

I. DEVELOPMENT OF THE ECOSYSTEM CONCEPT

The concept of the ecosystem as a functioning unit in the natural world is a relatively recent one. The term ecosystem was coined by the British ecologist Tansley in 1935 and has since become a common word in science and with the public. An ecosystem encompasses all the organisms of a given area and their relationships with one another and the physical or abiotic environment. The ecosystem contains the linkages and dynamic interactions between life and the environment, many of which are essential to society. A focus on the ecosystem as the unit of study represents a shift from studying the ecology and behavior of individual organisms and species (natural history) to the study of processes and how they influence or are influenced by organisms and their interactions with the environment.

Dividing the complexity of nature into convenient units of study is required for scientific investigation but can present problems. Ecological systems can be...
ECOSYSTEM FUNCTION, PRINCIPLES OF

organized in a hierarchy of increasing levels of organization and complexity: individual, population, species, community, ecosystem, landscape, and biome. The size (scale) of an ecosystem is defined by the purposes of the study. Ecosystems may have distinct boundaries as in the case of a lake or a watershed. More often, the boundaries of one ecosystem (a forest) may grade gradually into another (a meadow) across an intermediate area called an ecotone. The ecotone is often a zone of higher diversity because it may be a suitable habitat for species from each of the adjoining ecosystems. At one extreme of scale, the earth is sometimes treated as an ecosystem. At the other extreme, the complex symbiotic community of organisms inhabiting the gut of a termite has all the functional properties of an ecosystem. The definition and delineation of an ecosystem has practical importance because ecosystems are increasingly seen as a functional unit for resource and conservation management purposes. It has become evident that the management of lands for sustained levels of ecosystem services and natural resources requires an understanding of how ecosystems function, how they respond to disturbance, and how the role of biodiversity is regulating their function and stability.

II. ECOSYSTEM FUNCTIONING AND ECOSYSTEM SERVICES

Society depends on the functioning of ecosystems for many essential ecosystem services on which we place economic and aesthetic value (Daily, 1997). Ecosystem functioning results from the collective activities of organisms and their life processes (production, consumption, and excretion) and the effects of these activities on the condition of the environment. These functions (services when they provide utility to humans) include production of food, fuel, and fiber, the cycling and purification of water, and the maintenance of organisms that have a role in ecosystem functioning or that provide products for human use (Table 1). Humans are rapidly changing the earth’s ecosystems and their services by altering land use or by harvesting biological resources (forest cutting and fisheries) (Vitousek et al., 1997). Approximately 40% of the earth’s primary production is diverted to human use. One consequence of these economic activities is an abrupt increase in the rate of change in biological diversity leading to species extinction, replacement of high-biodiversity ecosystems with less diverse managed systems, and invasions of natural ecosystems by exotic species. This pattern of ecosystem change has raised serious concern that the functioning and stability of our global ecosystem are threatened by the loss of biodiversity.

A. What Do Ecosystem Scientists Study?

Ecosystems share certain characteristics and functions that allow scientists to study ecosystem types (e.g., deciduous forest, temperate grassland, arctic tundra, coral reef, and deep-ocean hydrothermal vents) that vary greatly in structure, biodiversity, and spatial extent. For example, all ecosystems require inputs of energy (usually solar) and a supply of the mineral elements (nutrients) essential for life. These inputs support many ecological processes operating at multiple scales. For example, sunlight, carbon dioxide, and water are inputs for the process of photosynthesis, which can be measured and studied at the scale of individual cells, a leaf, the plant canopy, or an entire ecosystem. Photosynthesis acting with other processes such as mineral uptake by roots combine to create an ecosystem function—primary productivity.

Scientists can discover basic principles about the behavior of ecosystems by studying the functions that very different ecosystems, such as the polar desert of Antarctica and the rangelands of the southwestern United States, share in common (Virginia and Wall, 1999). The movement of energy and materials within and between ecosystems and the role of organisms in mediating these processes are the parameters used by

ecosystem scientists to compare the functioning of ecosystems and their responses to disturbance. Some of the important processes and functions central to the integrity and sustained activity of an ecosystem are summarized in Table II. Ecosystem scientists study the rate at which ecosystems remove carbon from the atmosphere by photosynthesis, store it in the soil as organic matter, and then return the stored carbon to the atmosphere during decomposition. They study how nitrogen is cycled through ecosystems to sustain continued plant productivity. Our knowledge of how carbon and nitrogen move in the ecosystem helps us to understand when an ecosystem has been seriously altered by humans, for example, by adding nitrogen in the form of air pollution (acid rain) and fertilizers.

Many basic principles provide insight into the functioning of ecosystems and their response to human use and disturbance. Here, we will consider some of the essential functions of ecosystems and examine the principles that govern their operation, with an emphasis on the role of organisms (biodiversity) in determining ecosystem functioning.

III. IMPORTANT ECOSYSTEM FUNCTIONS

A. Ecosystem Productivity

A central process of most ecosystems is photosynthesis, the capture of solar radiation and its conversion to stored chemical forms (biomass). Plants require sunlight, water, and essential nutrients for the processes of photosynthesis. Photosynthesis is coupled with other plant processes that result in plant growth, i.e., the accumulation of biomass. Primary productivity, the change in plant biomass per unit area and time, is an important index of ecosystem function. Primary productivity (often referred to as ecosystem productivity) has been related to plant species diversity as well as the diversity of organisms (soil biota) that influence the availability of limiting resources. Humans depend on ecosystem productivity as the basis of our agriculture and forestry and fisheries. Thus, factors that alter ecosystem productivity (e.g., climate change and biodiversity loss) affect us directly.

Ecosystems with high rates of primary productivity have favorable amounts of the resources required for plant growth and optimal climate. These systems also tend to have higher diversity (Table III). The highest rates of terrestrial ecosystem productivity are seen in the tropics, where temperature and moisture are favorable for plant growth throughout the year. In contrast, water-limited hot and cold deserts have much lower productivity, averaging less than 10% of that of tropical systems.

1. Limits to Ecosystem Productivity

A basic principle invoked to explain variation among ecosystems in their productivity is Liebig's Law of Minimum. Justus Liebig formulated this concept during pioneering studies of the mineral nutrition of plants in the early 1800s. He found that addition of a single "limiting element" to a soil would increase plant growth. Once this element was in sufficient supply, another mineral element would have to be supplied in increased amounts to stimulate additional increases in plant growth. From these observations, he proposed that a limiting factor was responsible for limiting the growth or reproduction of an organism or population. This

* Ecosystem productivity and biodiversity are often positively related.
factor might be a chemical factor (a growth-stimulating nutrient such as nitrogen), a physical factor such as moisture, or a biological factor such as the presence of a competing species. Thus, any change in a limiting factor is expected to have large effects on ecosystem functioning.

There are many examples in which a change in a limiting factor alters ecosystem function. The large increase in the amount of nitrogen cycling in the environment from fertilizers and fossil fuel should have significant effects on rates of ecosystem functions since nitrogen frequently is the primary limiting element for plant growth in terrestrial ecosystems. Humans have doubled the rate of nitrogen inputs to ecosystems with increases in carbon storage and declines in biodiversity (Vitousek et al., 1997). In fact, the forests of the northeastern United States may have reached "saturation" in their ability to absorb and retain anthropogenic inputs of nitrogen.

Are plant species diversity and primary production related? Ecologists are accumulating evidence from experiments in controlled growth facilities and in the field that ecosystem primary productivity increases with increasing plant species diversity. The theoretical basis for the expectation that productivity and diversity should be related derives from an understanding of how limiting resources (water and nutrients) are distributed in ecosystems and an appreciation for the diversity of physiological or "functional" traits that organisms have evolved to capture and utilize these resources for growth. Differences between plant species in rooting depth, phenology (seasonality of growth), photosynthetic rates, and other physiological traits allow multispecies communities to more fully utilize the available resources.

The ability of diverse plant communities to obtain higher productivity than low-diversity systems is demonstrated in traditional (low-input) agriculture in which polycultures (multiple-species plantings) often have higher yields than single-species plantings (mono-cultures) (Gliessman, 1998). For example, corn (Zea mays) yields at comparable densities are higher when corn is grown in the presence of nitrogen-fixing beans (Vicia spp.). The bean crop forms a symbiotic association with bacteria that "fix" atmospheric nitrogen (N₂) to other inorganic forms (ammonia and NH₃) usable by plants. The nitrogen fixed by the bean crop improves the overall supply of this limiting element in the soil and increases the growth of the interplanted corn. The functioning provided by the diverse corn–bean–nitrogen-fixing bacteria association is often replaced in intensive agriculture by applying inorganic nitrogen fertilizers. With external inputs (fertilizers) the corn monoculture can produce higher yields than can the polyculture. Substituting an industrial source of nitrogen for a biological source has environmental costs resulting from the production and combustion of fossil fuels used to produce fertilizers. In addition, overapplication of fertilizers is a major source of water pollution in surface and groundwaters.

There are similar examples of diversity influencing productivity in natural ecosystems. In a California grassland ecosystem, Hooper and Vitousek (1997) manipulated the number of plant functional groups in a community (early vs late-season forbs, perennial grasses, and nitrogen-fixing plants) in combinations of one to four groups in a given plot. They found that the number of plant functional groups was not the main factor that determined productivity. Rather, certain functional characteristics of individual species within functional groups contributed more to ecosystem productivity than overall diversity of the plot. This study points to the complexity of trying to simply relate species diversity to function. As a general principle, ecologists recognize that some species play particularly important roles in regulating important ecosystem functions such as productivity and nutrient cycling.

B. Keystone Species

Certain species, termed keystone species, have a disproportionate influence (relative to their biomass) on ecosystem functioning. The loss of a keystone species will produce a cascade of effects on the diversity and function of the remainder of the ecosystem (Bond, 1993). Consequently, since keystone species can control ecosystem diversity and associated ecosystem functions, they and the habitats they live in often receive high priority in conservation management plans. There are many well-documented studies of keystone species and how they interact with ecosystem functioning, e.g., the North Pacific sea otter preys on sea urchins, which consume kelp. In the absence of the keystone predator, sea urchin populations increase and create areas devoid of kelp and, consequently, the myriad of fish and other species that depend on the kelp forest (Fig. 1). This is an example of a food web, the representation of trophic (feeding) relationships between species in an ecosystem.

There are many examples of keystone species in terrestrial ecosystems. A large change in African elephant numbers has dramatic effects on the diversity
and structure of the vegetation types (savanna woodlands and forests) they consume, altering ecosystem productivity, soil nutrient cycles, and plant community diversity. The much smaller tsetse fly shares the elephant’s habitat and also has the attributes of a keystone species. The tsetse fly is the vector for the human disease sleeping sickness (African trypanosomiasis). This biting fly also influences the behavior of large herbivores that tend to avoid heavily infested areas. Consequently, herbivore-related impacts on plant communities and associated ecosystem functions are altered in tsetse-occupied ecosystems. This small insect may control the biodiversity of large tracts of Africa through another mechanism. Diverse native ecosystems have been “protected” from agricultural development and species loss because humans avoid regions where the tsetse and therefore sleeping sickness are endemic.

C. Nutrient Cycling

The sustained functioning of any ecosystem requires a minimum number of species to develop the intricate relationships between producers, consumers, and decomposers that regulate the flow of energy and nutrients. The productivity of all ecosystems is dependent on the cycling of essential elements. The movement and biological transformations of organic matter and nutrients are mediated by biota, especially those found in soil and sediments (Wall and Virginia, 1999). Therefore, changes in the biodiversity of ecosystems can alter biogeochemical processes.

1. Succession

Scientists study the process of ecological succession (ecosystem change with time, often in response to disturbance) in part to untangle relationships between biodiversity and function. Although not all ecosystems follow a predictable pathway as they develop in time, examples of succession highlight the linkage between organisms and diversity and ecosystem function. They include the recovery of a forest after harvest or following damage by a hurricane, the reestablishment of grassland following fire, and the old-field succession of natural vegetation reclaiming abandoned agricultural land. During succession, ecosystems change in generally predictable ways as they accumulate species, increase in biomass, and gain structural complexity. Odum (1969) proposed a model of ecological succession (development) that relates ecosystem diversity, structure, and functioning as ecosystems redevelop and “mature” following disturbance (Table IV). Odum’s model related the stability (constancy) of function and the conservation of nutrients to increasing diversity—themes that are at the center of biodiversity and ecosystem research today.

*Based on Odum (1969)*
The relationships represented in Odum's (1969) model between ecosystem function and diversity are elucidated in the Hubbard Brook watershed experiment (Likens and Bormann, 1995). One of the first long-term ecosystem studies, the Hubbard Brook project began in 1963 in the White Mountains of New Hampshire. The study was designed to understand the process of forest recovery following harvest with a focus on ecosystem functions related to production, nutrient cycling, and nutrient loss. Measurements of the mature intact deciduous forest showed that less than 0.1% of the nitrogen contained in living forest biomass and dead organic matter in the soil and litter left the site in stream flow.

A nutrient cycle in which outputs are low and internal recycling of nutrients is high (the loop from soil to vegetation and back to soil) is called a closed nutrient cycle. After the unperturbed patterns of growth and nutrient cycling were known, an entire Hubbard Brook watershed was clear-cut. What followed was a dramatic change in ecosystem functioning. Stream flow increased by approximately 40% because water use by plants had been nearly eliminated by the forest harvest. The previously ‘closed’ nutrient cycle of this forest became ‘open.’ After clear-cut the concentrations of nitrogen (nitrate) in the stream water draining the watershed increased approximately 60-fold. Concentrations of elements that are important to the biology of the ecosystem leaked into the streams and were exported from the ecosystem. Elements not essential to plant growth or required in very small amounts (e.g., sodium) were not lost to the same degree, indicating their cycling was not regulated by biotic activity of the forest. Odum (1969) predicted that nutrient losses would decline with increasing plant biomass and function. After the Hubbard Brook forest was allowed to regrow (undergo succession), nutrients resumed being absorbed by plants and nutrient losses to streams declined to near baseline levels. The Hubbard Brook ecosystem experiment informed forest management practices by providing a better understanding of how forest removal and regrowth affect the retention of soil nutrients and therefore the long-term productivity and diversity of the ecosystem.

**D. Ecosystem Stability**

Ecosystems are dynamic. They experience change in species composition and function in response to variations in climate and an array of disturbances. Fire, flood, drought, frost, and biological events such as the outbreak of pathogens and pests can ‘stress’ ecosystems and alter their condition. Ecosystems vary widely in their responses to disturbance. The ability of an ecosystem to withstand stress without a loss of function (resistance) or to recover rapidly from disturbance (resilience) is an important ecosystem trait. Some ecosystems, such as tropical forests, appear very stable (high resistance and resilience) and their functioning is little affected by variations in factors external to the system (e.g., weather). Ecosystems with high resilience are buffered against perturbation. Many ecosystems, however, show large decreases in productivity and biodiversity when disturbed. These ecosystems are ‘fragile’ and have low resistance.

The relationship between ecosystem stability and diversity has been the subject of many field studies and theoretical tests using mathematical modeling. Ecologists have hypothesized that ecosystems with high biodiversity are more resistant (will experience less change) in response to a given level of disturbance and will also exhibit resilience—a high rate of recovery to predisturbance functioning (Folke et al., 1996).

Does diversity influence the stability of ecosystem functioning? There is experimental evidence that it can do so (Chapin et al., 1997). Several mechanisms have been proposed and tested to varying degrees to examine this relationship (Chapin et al., 1997). Higher species diversity means that the trophic structure (feeding relationships among species) of the ecosystem is more complex, providing alternate pathways for energy flow within and between trophic levels (producers, consumers, and decomposers). Alternative pathways for energy transfers within the ecosystem could increase resistance to disturbance (species loss). Naeem and Li (1997) tested the hypothesis that redundancy (multiple species with similar functions in a food web) would stabilize ecosystem functioning by creating experimental microcosms with a varying number of species in each functional group. The simple systems contained producers (algae), decomposers (bacteria), and a primary and secondary consumer trophic level (protozoa)—the trophic structure of a typical aquatic ecosystem. Nutrient levels, light, and the number of species per trophic level were manipulated, and the biomass and density of the producers and decomposers were measured as an indicator of ecosystem functioning. As the number of species in a trophic level increased, the biomass and density of replicate communities were more consistent. Thus, the communities with more species were more predictable in function (biomass production) and had higher reliability, i.e., the probability that an ecosystem will pro-
provide a given level of performance over a specified period of time. Higher species diversity may ensure functioning by reducing the risk of invasion by species that have the capacity to alter the structure or function of the ecosystem. An example is the higher resistance of species-rich natural systems to pest outbreaks compared to low-diversity agricultural ecosystems growing under the same environmental conditions. The spatial arrangement of individuals in an ecosystem can affect their risk to disease, predation, or consumption. In higher diversity systems, the mean distance between individuals of the same species is on average greater than that of low-diversity systems. The wider spacing of individuals acts to slow the movement of pathogenic organisms, which should limit the occurrence of pest outbreaks that alter the performance of the ecosystem. These and other observations lead to the general expectation that diversity increases the resistance of ecosystems to disturbance.

The benefits of biodiversity to ecosystem functioning should be multiple since the processes of production and nutrient cycling are coupled by the biological interactions of organisms. The response of a Minnesota grassland to a severe drought (disturbance) illustrates this principle (Tilman et al., 1996). In 1987 and 1988, a drought decreased productivity of the grassland. The species diversity of experimental plots prior to the drought explained the degree of productivity loss. Diversity in productivity was about 50% decline in productivity, whereas productivity in the least diverse plots declined by more than 90%. The greater resistance of the higher diversity plots resulted from compensatory increases in productivity shown by drought-resistant species. The more diverse plots also had lower concentrations of nitrate in the rooting zone, indicating a more efficient use of this limiting resource.

This experiment demonstrates that species diversity has an effect on productivity and nutrient cycling and that declining species diversity influences these functions. However, we lack an understanding of the mechanisms producing these patterns of ecosystem response to disturbance and biodiversity change. Increasing diversity may increase the chance that a single drought-adapted and productive species will be present in the community, ensuring relatively high productivity. Alternatively, higher diversity may provide for a more efficient utilization of limiting resources, as suggested by the lower soil nitrate in more diverse plots. Before the basic relationships between biodiversity and ecosystem functioning can be more fully formalized, we need more detailed information on the critical levels (thresholds) of diversity associated with specific ecosystem functions and how environmental conditions operating over time alter their relationship (Folke et al., 1996).

IV. CONCLUSIONS

Humans have become major agents of environmental change and influence the biodiversity and structure of ecosystems in many ways. Air pollution, clearing of natural systems for agriculture, forestry and urban development, the spread of exotic species, changes in the composition of the atmosphere, and other anthropogenic influences are altering ecosystem functioning. By changing ecosystem biodiversity and altering the processes that biota mediate, we significantly decrease the ability of ecosystems to provide services and resources for our use. The management of ecosystems for sustained levels of services and the restoration of damaged ecosystems will require greater knowledge about the role that species play in ecosystems functions related to production and nutrient cycling. Although we cannot know with certainty the roles of most species in ecosystems, it is prudent to assume that all biodiversity is essential to ecosystem function and stability and should be valued and protected.

GLOSSARY

ecosystem services The wide array of conditions and processes through which ecosystems, and their biodiversity, confer benefits on humanity; these include the production of goods, life-support functions, life-fulfilling conditions, and preservation of options.
marginal value Economic value of the next incremental unit of something. In this context, marginal values are those associated with managing the next small unit of an ecosystem in a particular way (e.g., preserving, rather than clearing, the next unit of forest).

ECOSYSTEM SERVICES ARE ESSENTIAL TO HUMAN EXISTENCE, and yet their supply is seriously threatened by the intensification of human impacts on the environment. This article provides an overview of issues concerning the identification, biophysical and economic characterization, and safeguarding of ecosystem services.

I. OVERVIEW

Human societies derive many benefits from natural ecosystems. These include the production of a diversity of ecosystem goods, or extractive benefits, such as seafood, timber, biomass fuels, and precursors to many industrial and pharmaceutical products. The harvest and trade of these goods represent an important and familiar part of the economy. Ecosystem services also include non-extractive benefits—fundamental life-support processes including pollination, water purification, renewal of soil fertility, and climate regulation. Ecosystem services include life-fulfilling functions, encompassing aesthetic beauty and the cultural, intellectual, and spiritual values derived from nature. Finally, preservation of the option to use these (or new) services in the future is also an important service in itself.

One way to appreciate the nature and value of ecosystem services is to imagine trying to set up a happy existence on the moon. Assume for the sake of argument that the moon miraculously already had some of the basic conditions for supporting human life, such as an atmosphere and climate similar to those on Earth. After packing one’s prized possessions, the big question would be, Which of Earth’s millions of species would be required to sustain the lunar colony?

Tackling the problem systematically, one could first choose from among all the species exploited directly for food, drink, spice, fiber and timber, pharmaceuticals, industrial products (such as waxes, lac, rubber, and oils), and so on. Even being selective, this list could
amount to hundreds, or even several thousand, species. The space-ship would be filling up before even begin-
ing to add the species crucial to supporting those at
the top of one’s list. Which are these unsung heroes? No one knows which—nor even approximately how
many—species are required to sustain human life. This
means that rather than listing species directly, you
would have to list instead the life-support functions
required by your lunar colony; then you could guess
at the types and numbers of species required to perform
each. At a bare minimum, other companions on the
spaceship would have to include species capable of
supplying a whole suite of ecosystem services that
Earthlings take for granted. Table I provides a classifi-
cation of important ecosystem services.

Armed with this preliminary list of services, one
could begin to determine which types and numbers of
species are required to perform each. This is no simple
task. Consider soil fertility. Soil organisms play impor-
tant and often unique roles in the circulation of matter
in every ecosystem on Earth, they are crucial to the
chemical conversion and physical transfer of essential
nutrients to higher plants, and all larger organisms,
including humans, depend on them. The abundance of
soil organisms is tremendous: under a square yard of
pasture in Denmark, for instance, the soil was found
to be inhabited by roughly 50,000 small earthworms
and their relatives, 50,000 insects and mites, and nearly
12 million roundworms. And that is not all. A single
gram (a pinch) of soil has yielded an estimated 30,000
protozoa, 50,000 algae, 400,000 fungi, and billions of
individual bacteria (Overgaard-Nielsen, 1955). Which
to bring to the moon? Most of these species have never
been subjected to even cursory inspection. Yet the so-
berefit fact of the matter is, as Ed Wilson put it: they
don’t need us, but we need them.

In the early 1990s, the first Biosphere 2 “mission”
carried out this thought experiment to the greatest de-
gree possible on Earth. Eight people were enclosed in
a 3.15-acre closed ecosystem, featuring agricultural land
plus a wide array of natural habitats (desert, savanna,
tropical forest, wetland, and even a miniature ocean).
The aim was to demonstrate a (mostly) closed system
that could supply people with their material needs for
two years. Yet in spite of an investment of over $200
million in the design, construction, and operation of
this model Earth (including $1 million in annual energy
inputs), it proved impossible to do so and the experi-
ment was shut down early in failure. Numerous un-
pleasant and unexpected problems arose, including a
fall in atmospheric oxygen concentration to 14% (the
level normally found at an elevation of 17,500 feet);
ECOSYSTEM SERVICES, CONCEPT OF

High spikes in carbon dioxide concentrations; nitrous oxide concentrations high enough to impair brain function; rapid species extinctions (including 19 of 25 vertebrate species and all pollinators, therebydooming most of the plant species to eventual extinction as well); overgrowth of aggressive vines and algal mats; and, to top it all off, population explosions of crazy ants, cockroaches, and katydids. Even heroic personal efforts on the part of the Biospherians did not suffice to make the system viable and sustainable for humans nor many nonhuman species, illustrating the tremendous expense and difficulty of replicating many basic ecosystem services (Cohen and Tilman, 1996).

Ecosystem services are generated by a complex of natural cycles, driven by solar energy, that constitute the workings of the biosphere—the thin layer near Earth’s surface that contains all known life. The cycles operate on very different scales. Biogeochemical cycles, such as the movement of the element carbon through the living and physical environment, are truly global and reach from the top of the atmosphere to deep into soils and ocean-bottom sediments. Life cycles of bacteria, in contrast, may be completed in an area much smaller than the period at the end of this sentence. The cycles also operate at very different rates. The biogeochemical cycling of carbon, for instance, occurs at a rate that is orders of magnitude faster than that of phosphorus, just as the life cycles of microorganisms may be many orders of magnitude faster than those of trees.

All of these cycles are ancient, the product of billions of years of evolution, and have existed in forms very similar to those seen today for at least hundreds of millions of years. They are absolutely pervasive, but unnoticed by most human beings going about their daily lives. Who, for example, gives a thought to the part of the carbon cycle that connects him or her to Earth’s surface that contains all known life. The cycles operate on such a grand scale and in such intricate and little-explored ways that most could not be replaced by technology.

Human activities are already impairing the flow of ecosystem services on a large scale. And in such intricate and little-explored ways that most could not be replaced by technology.

In addressing these points in more detail, we shall first consider briefly the history of concern for ecosystem services. Then we shall explore the functioning of a small set of services in biophysical terms; the economic characterization of ecosystem services is discussed elsewhere in the Encyclopedia. Finally, we will examine the utility of the Ecosystem Services Framework, in the abstract and then in operation, reviewing recent developments in the safeguarding of ecosystem services.

II. HISTORY

Interestingly, the nature and value of Earth’s life-sustaining ecosystems have been illuminated primarily through their disruption and loss. Thus, for instance, deforestation has demonstrated the critical role of forests in the hydrological cycle—in particular, in mitigating floods, droughts, the erosive forces of wind and rain, and siltation of waters and irrigation canals. Release of toxic substances, whether accidental or deliberate, has revealed
the nature and value of physical and chemical processes, governed in part by a diversity of microorganisms, that disperse and break down hazardous materials. Thinning of the stratospheric ozone layer sharpened awareness of the value of its service in screening out harmful ultraviolet radiation.

A cognizance of ecosystem services, expressed in terms of their loss, dates back at least to Plato around 400 B.C. and probably much earlier:

What now remains of the formerly rich land is like the skeleton of a sick man with all the fat and soft earth having wasted away and only the bare framework remaining. Formerly, many of the mountains were arable. The plains that were full of rich soil are now marshes. Hills that were once covered with forests and produced abundant pasture now produce only food for bees. Once the land was enriched by yearly rains, which were not lost, as they are now, by flowing from the bare land into the sea. The soil was deep, it absorbed and kept the water . . . , and the water that soaked into the hills fed springs and running streams everywhere. Now the abandoned shrines at spots where formerly there were springs attest that our description of the land is true.

—PLATO

Mooney and Ehrlich (1997) trace modern concern for ecosystem services to George Perkins Marsh, a lawyer, politician, and scholar. Indeed, his 1864 book Man and Nature describes a wide array of services, again, often expressed in terms of their loss. Remarkably on the terrain of the former Roman Empire, he notes that it “is either deserted by civilized man and surrendered to hopeless desolation, or at least greatly reduced in both productiveness and population” (p. 9). He goes on to describe the reduction of hydrological services: “Vast forests have disappeared from mountain spurs and ridges, the vegetable earth . . . [is] washed away; meadows, once fertilized by irrigation, are waste and unproductive, because . . . the springs that fed them dried up; rivers famous in history and song have shrunk to humble brooklets” (p. 9). Marsh also made connections between deforestation and climate: “With the disappearance of the forest, all is changed. At one season, the earth parts with its warmth by radiation to an open sky—receives, at another, an immoderate heat from the unobstructed rays of the sun. Hence the climate becomes excessive, and the soil is alternately parched by the fervors of summer, and seared by the rigors of winter. Bleak winds sweep unrestrained over its surface, drift away the snow that sheltered it from the frost, and dry up its scanty moisture” (p. 186). Finally, he even wrote of decomposition services: “The carnivorous, and often the herbivorous insects render an important service to man by consuming dead and decaying animal and vegetable matter, the decomposition of which would otherwise fill the air with effluvia noxious to health.” (p. 98)

Following World War II, other eloquent writers on the environment emerged, including Fairfield Osborn (Our Plundered Planet, 1948), William Vogt (Road to Survival, 1948), and Aldo Leopold (A Sand County Manac and Sketches from Here and There, 1949). Each discusses ecosystem services without using the term explicitly. In The Population Bomb (1968), Paul Ehrlich describes anthropogenic disruption of ecosystems and the societal consequences of doing so, addressing the need to maintain important aspects of ecosystem functioning. Along these lines, the Study of Critical Environmental Problems (1970) presents a list of key “environmental services” that would decline with a decline in “ecosystem function,” including many in Table I. This list was expanded upon by Holdren and Ehrlich (1974). By the early 1980s, efforts were initiated to investigate two questions: the extent to which ecosystem function (and the delivery of services) depends on biodiversity, and the extent to which technological substitutes could replace ecosystem services. The first question is addressed elsewhere in this Encyclopedia, and the second question was tackled by Ehrlich and Mooney (1983). Work on these topics proliferated and, in 1997, a collective effort was made to synthesize the wealth of scientific information that had accumulated on the functioning of ecosystem services, with a preliminary exploration of their economic value, and of key issues meriting further work (Daily, 1997).
a sevenfold increase or more in some countries. It is difficult to forecast how these needs will be met. Whatever course is taken, it is reasonable to expect that growing human pressures will continue to alter ecosystems, probably very dramatically.

At the same time, food production is highly dependent on ecosystem services. In what ways? Let us consider four types of services that are key to agriculture: climate stability, services supplied by soil, pollination, and pest control. In each case, an overview of the functioning of the service will be given, along with a general assessment of its importance.

A. Climate Stability

Earth’s climate has fluctuated tremendously since humanity came into being, but it has been relatively stable since the Invention of agriculture around 10,000 years ago. At the peak of the last ice age 20,000 years ago, for example, much of Europe and North America were covered by mile-thick ice sheets. Even relatively recently, from 1530 to 1850, Europe was significantly cooler during a period known as the Little Ice Age. Many of these changes in climate are thought to be caused by alterations in Earth’s orbital rotation or in the energy output of the sun, or by sudden perturbations (such as violent volcanic eruptions and asteroid impacts) or more gradual tectonic events (such as the development of the Himalayas). Remarkably, climate has been buffered enough through all of these changes to sustain life for at least 3.5 billion years—although the increases in climate change is thought to have induced the past mass extinctions. Human activities now threaten to induce rapid climatic change, with wide-reaching consequences for society.

Climate plays a major role in the evolution and distribution of life over the planet. Most scientists would also agree that life itself is a principal factor in the regulation of global climate, helping to dampen the effects of episodic perturbations through negative feedback mechanisms that offset climate oscillations with changes in greenhouse gas concentrations. For instance, natural ecosystems may have helped to stabilize climate by removing CO₂ from the atmosphere. The relative influence of stabilizing and destabilizing feedbacks remains uncertain; what is clear is that climate and natural ecosystems are tightly coupled, and maintaining the stability of that coupled system is an important ecosystem service.

Ecosystems also help moderate regional and local weather. For instance, evapotranspiration of plants in the morning contributes moisture to the atmosphere that then falls in thunderstorms in the afternoon, damping both moisture loss and surface temperature rise. In the Amazon, for example, 50% of the mean annual precipitation is recycled via evapotranspiration by the forest itself. Amazon deforestation could so dramatically reduce precipitation that the forest might be unable to reestablish itself following large-scale destruction. Temperature extremes are also moderated by forests, which provide shade and surface cooling and also act as insulators, blocking searing winds and trapping warmth by acting as a local greenhouse agent.

B. Services Supplied by Soil

The ecosystem services supplied by soil are so tightly interrelated as to make any discrete classification arbitrary. We shall briefly touch on six services here: (i) physical support of plants; (ii) retention and delivery of nutrients to plants; (iv) disposal of wastes and dead organic matter; (v) regulation of major element cycles.

An enormous amount of water, about 119,000 km³, falls annually on Earth’s land surface—enough to cover the land to an average depth of 1 meter. Much of this water is soaked up by soils and is gradually metered out to plant roots and into aquifers and surface streams. Without soil, rainfall would rush off the land in flash floods. Plant foliage, roots, and residues shield the soil from the full, destructive force of raindrops, holding it in place. Rain on denuded landscapes compacts the surface and turns soil rapidly to mud (especially if it has been loosened by tillage), which clogs surface cavities in the soil, reduces infiltration, increases runoff, and further enhances clogging in a positive feedback. Detached soil particles are splashed downslope and carried off by running water. Soil also shelters seeds and provides physical support
as they sprout and mature into adult plants. The energetic costs to plants of packaging and storing seeds and of anchoring plant roots would be enormous without soil. Human-engineered hydroponic systems grow plants in the absence of soil and their cost provides a lower-bound index to the value of this service. The physical support trays and stands used in such operations amount to about U.S. $55,000 per hectare.

Third, soil retains and delivers nutrients to plants. Tiny soil particles, primarily bits of humus and clays, carry a surface electrical charge that is generally negative. This property holds positively charged nutrients (cations) near the surface, in proximity to plant roots, allowing them to be taken up gradually. Otherwise, they would quickly be leached away. Soil also acts as a buffer in the application of fertilizers, holding the fertilizer ions on soil exchange sites until required by plants.

Fourth, soil plays a paramount role in the decomposition of dead organic matter and wastes, in the process rendering harmless many potential human pathogens. People generate a tremendous amount of waste, including household garbage, industrial waste, crop and forestry residues, and sewage from their own populations and their billions of domesticated animals. A rough approximation of the amount of dead organic matter and waste (mostly agricultural residues) processed each year is 130 billion metric tons, about 30% of which is associated with human activities. Fortunately, there is a diverse array of decomposing organisms—ranging from vultures to tiny bacteria—that earn their living by extracting energy from the large, complex organic molecules found in many types of waste. The simple inorganic chemicals that result from natural decomposition are eventually returned to plants as nutrients. Thus the decomposition of wastes and the recycling of nutrients, the fifth service, are two aspects of the same process. The fertility of soils—that is, their ability to supply nutrients to plants—is largely the result of the activities of diverse species of bacteria, fungi, algae, crustacea, mites, termites, springtails, millipedes, and worms, all of which, as groups, play important roles. Some bacteria are responsible for “fixing” nitrogen (a key element in proteins), drawing it out of the atmosphere; the latter cause acid precipitation, eutrophication, and contamination of groundwater and surface drinking water sources by high nitrate-nitrogen levels.

C. Pollination

Animal pollination is required for the successful reproduction of most flowering plants, including both wild plants and about 70% of the agricultural crop species that feed the world. Over 100,000 different animal species (including bats, bees, beetles, birds, butterflies, and flies) are known to provide “free” pollination services, which maintain croplands, backyard gardens, meadows, forests, and rangelands. The availability of these pollinators depends on the existence of a wide variety of habitat types needed for their feeding, successful breeding, and completion of their life cycles.

Considering the proportions in which we consume different crops, about one-third of human food comes from animal-pollinated plants. Critical grain crops, such as rice and wheat, are not animal-pollinated. Without natural pollination services, yields of other important crops would decline precipitously and many wild plant species would become extinct. In the United States alone, billions of dollars of crops would be lost (annually) without the services of wild, native pollinators—those sustained by natural habitats adjacent to farmlands. Pollination by honeybees, originally imported from Europe, is extremely important as well, but they are presently in decline, making pollinators from natural ecosystems all the more important. Management of the honeybee in the New World is currently threatened by the movement of, and hybridization with, the aggressive African strain of honeybee that was accidentally released in Brazil in 1956. Diseases of honeybee colonies are also causing a marked decline in the number of managed colonies. Meanwhile, the diversity of pollinators available to both wild and domesticated plants is diminishing: more than 60 genera of pollinators include species now considered to be threatened, endangered, or extinct.
D. Natural Pest Control Services

Humanity’s competitors for food, timber, cotton, and other fiber are called pests; these include numerous herbivorous insects, rodents, fungi, snails, nematodes, and viruses. These pests destroy an estimated 25% (up to as much as 30%) of crops, before and after harvest. In addition, numerous weeds compete directly with crops for water, light, and soil nutrients, further limiting yields.

Chemical pesticides, and the strategies with which they are applied, can have harmful unintended consequences. First, resistance is now found in over 500 insect and mite pests, over 100 weeds, and in about 150 plant pathogens. This means that achieving a fairly constant level of pest control requires applying higher and higher doses of pesticides—or continuously developing new, more powerful chemicals to combat evolving pest defenses. Second, populations of natural pest enemies are decimated by heavy pesticide use. Not having the same evolutionary experience with plant chemicals that the pests themselves have had, and typically having much smaller population sizes (being higher on food chains), natural predators are often more susceptible to synthetic poisons than are the pests. Destruction of predator populations leads to explosions of their prey and the “promotion” of species previously not classified as pests to pest status. In California in the 1970s, for instance, 24 of the 25 most important agricultural pests had been “created” by the overuse of pesticides. Third, exposure to pesticides and herbicides may pose serious health risks to humans and many other organisms, the recently discovered declines in human sperm counts may be attributable in part to such exposure.

Fortunately, an estimated 99% of potential crop pests are controlled by natural enemies, including many birds, spiders, parasitic wasps and flies, ladybugs, fungi, viral diseases, and numerous other types of organisms. These natural biological control agents save farmers and society billions of dollars annually by protecting crops and reducing the need for chemical control.

IV. THE ECOSYSTEM SERVICES FRAMEWORK

All of these services are presently under threat. When human activities approach or exceed the environment’s capacity to sustain them, growth in those activities is rarely brought to an immediate halt. Rather, the people so engaged suddenly find themselves confronted with a set of trade-offs in the allocation of resources to competing uses and users. These trade-offs are becoming increasingly vexing and difficult to resolve, from both ethical and practical perspectives. They involve our most important ideals (such as ensuring a prosperous future for our children), our oldest tensions (such as between individual and societal interests), and sometimes our bloodiest tendencies.

At the local level, allocation of land or water to competing activities often involves a zero-sum game. This is apparent in the widespread loss of water and land from native habitat to farms, and increasingly to urban and industrial uses. On what basis should such allocations be decided? How can individual preferences for alternative allocations be aggregated fairly? How can the costs and benefits of alternative schemes be distributed fairly? And how can the parties with the most at stake—future generations—be represented at the bargaining table? At the international level, these questions are writ large. Consider efforts to allocate among nations permits to produce chlorofluorocarbons, to harvest certain marine fish stocks, or to use the global carbon dioxide sink. How these questions are decided will profoundly influence the willingness of nations and individual actors to make and comply with agreements.

The ecosystem services approach provides a conceptual framework for helping to resolve these trade-offs. The framework recognizes natural ecosystems and their biodiversity as capital assets that, if properly managed, will yield a stream of life-support goods and services over time. Relative to physical, human, or financial capital, renewable natural capital (embodied in ecosystems) is poorly understood, typically undervalued, scarcely monitored, and—in many important cases—undergoing rapid depletion. Up until now, there has been little incentive to measure or manage natural capital: it has been treated as essentially inexhaustible.

Measuring natural capital involves assessing both its stock and its importance to society. Neither is simple to do, but the latter is particularly difficult: valuation in economic or other (e.g., cultural, spiritual) terms involves resolving fundamental philosophical issues (such as the underlying bases for value), the establishment of context, and the defining of objectives and preferences, all of which are inherently subjective. Even after doing so, one is faced with formidable technical difficulties with interpreting information about the world and transforming it into a quantitative measure of value. Just as the full value of a human being cannot be captured in economic terms (on the basis of his or her wage-earning power, or the economic value of his or her constituent materials), there exists no absolute...
value of ecosystem services waiting to be discovered and revealed to the world by a member of the intellectual community. Other entries in the Encyclopedia discuss these issues and describe alternative empirical valuation techniques, their applicability to different types of ecosystem services, and the advantages and limitations of their use.

As a whole, ecosystem services have infinite value because human life could not be sustained without them. The evaluation of the trade-offs currently facing society, however, requires that we estimate the marginal value of ecosystem services (the value yielded by an additional unit of the service, all else held constant) to determine the costs of losing—or the benefits of preserving—a given amount or quality of services. The information needed to estimate marginal values is also difficult to obtain and is presently unavailable for many aspects of the services. Nonetheless, even imperfect measures of their value, if understood as such, may prove superior to ignoring ecosystem services altogether, as is generally done in decision making today.

V. SAFEGUARDING

How can the Ecosystem Services Framework be made operational to ensure the safeguarding of key services? Here success hinges on the institutional framework in which valuation is done and incorporated into policy. Valuation is not a solution in itself—it is merely one way of organizing information in the much larger politics of decision making. The actual safeguarding of ecosystem services will require the establishment (or strengthening) of institutions that reward such action. Institutions must be tailored to local ecological, economic, and cultural circumstances and provide a payoff for conservation in a relatively short and certain time frame to be effective (see Heal, in press).

The management by New York City of its drinking water quality offers a model example of how ecosystem services can be characterized (both biophysically and economically), monitored, and safeguarded. The city’s water originates in the Catskill Mountains, about a hundred miles to the north of the city, and was once considered so pure and salubrious that it was bottled and sold throughout the Northeast. In recent years, the natural purification system of the Catskills has been overwhelmed by sewage and agricultural runoff, resulting in a reduction in water quality below minimum drinking standards. The United States Environmental Protection Agency (EPA) required that the city remedy this problem.

The city administration first considered replacing the natural system with a filtration plant, but found that it would cost an estimated $6–8 billion in capital plus $300 million in annual operations. These high costs prompted investigation of an alternative solution, namely, restoring and safeguarding the natural purification services of the Catskills. This would involve the purchase of land in and around the watershed to protect it, as well as subsidizing several changes on privately owned land: the upgrading of sewage treatment plants, the improvement of farming practices, and “environmentally sound” economic development. The total cost of this option was estimated at about $1.5 billion.

Thus, New York City faced a choice of investing $6–8 billion in physical capital or $1.5 billion in natural capital. In spite of some political opposition, the latter option clearly appeared to be the more attractive, so the city floated an Environmental Bond Issue to fund its implementation. This financial mechanism captures the important economic and public health values of a natural asset (the watershed) and distributes them to those assuming stewardship responsibilities for the asset and its services.

The Catskills supply many other valuable services, such as flood control, carbon sequestration (locking up, in forests and the soils beneath them, carbon dioxide, an important greenhouse gas), biodiversity conservation, and—perhaps above all—beauty, serenity, and spiritual inspiration. Moreover, these services benefit others besides water consumers in New York City. It would be absurd to try to express the full ecosystem service value of the Catskills in a dollar figure. In this case, fortunately, there was no reason to try: even a lower-bound estimate of the value of the natural asset was sufficient to induce adoption of a conservation policy.

The challenge is to extend this model to other geographic locations and to other services. In other places, water quality is certainly a growing concern: the United Nations Environment Programme reports that most diseases in the less-developed world are caused by contaminated water, and that 30% of people in these countries suffer from one or more water-related diseases. An estimated 10–15% of the U.S. population currently consumes water from systems that violate EPA contaminant standards. The EPA forecasts that communities will have to spend $1–40 billion over the next 20 years to maintain drinking water quality at minimum required standards.

To evaluate the potential for extending the New York City model, Walter Reid posed this question: How much land could be protected with an economic justification, using water quality as a major goal? A first-order ap-
proximation suggests that the area would be significant: 10% of U.S. land area and 14% of global land area under current population sizes. Reid further points out that hydroelectricity generation is another important good whose supply, like that of drinking water, economically justifies watershed protection in many instances. Costa Rica, for example, derives 99% of its electricity from hydroelectric plants; most of the water generating this electricity flows from protected areas. In 1999, Costa Rica established a small tax on water and electricity use, the revenues from which are now recycled into managing the protected areas to limit erosion and sedimentation and to maintain high water flows. Numerous ancillary benefits accrue in this scheme, including protection of valuable flood control, biodiversity conservation, and ecotourism services.

To extend this model to other places and other services, appropriate educational, financial, and legal institutions, tailored to cultural and economic circumstances, will be required. Without these, statements from ecologists and economists that ecosystems are important and valuable assets will accomplish little. Promising new institutions for safeguarding ecosystem services have emerged in a wide array of cultures and economies (e.g., Australia, Madagascar, the United States, Vietnam); at a variety of scales, from local to international; and among governments, nongovernmental organizations, and private sectors. The services safeguarded by these emerging institutions include pollination; pest control; water supply for drinking, for irrigation, and for hydropower generation; maintenance of soil fertility; sustainable harvesting of tropical timber; provision of aesthetic beauty; and even decomposition (of orange peels produced by Del Oro, an orange juice company in Costa Rica, which are carefully distributed in a reserve area).

VI. CONCLUSIONS

An enormous payoff could result from further research in the characterization (biophysical and economic) of ecosystem services and in the development of institutions for their safeguarding. A series of basic questions, spanning a wide array of disciplines, beg addressing in this area. With emphasis here on biophysical characterization, they include:

• Which ecosystems supply what services? What is the scale of delivery, transport, and consumption of the services?
• What are the relationships between the quantity or quality of services and the condition (e.g., relatively pristine versus heavily modified) or areal extent of the ecosystem supplying them? Where do critical thresholds lie?
• To what extent do the services depend on biodiversity?
• To what extent, and over what time scale, are the services amenable to repair?
• How interdependent are the services? How does safeguarding or damaging one influence the functioning of others?
• What indicators could be used to monitor accurately and efficiently the changes in the supply or quality of ecosystem services?
• How effectively, and on how large a scale, can existing or foreseeable human technology substitute for ecosystem services?
• What are the main sources of uncertainty regarding ecosystem services, and how important are they? How can the uncertainty best be quantified and incorporated into policy?
• How can economic principles and tools best be brought to bear on the management of natural capital?
• Given that many values of ecosystems lie mostly in the future (and will always lie mostly in the future), how should future benefits be valued, in economic, cultural, or other terms?
• What financial, legal, and other social institutions are needed to safeguard critical ecosystem services? How can their development be catalyzed?

While a great deal is known about the functioning of ecosystems and the supply of services in general, abstract terms, there is a paucity of information on particular, local ecosystems and economies. Very little is known about marginal values (the net benefit or cost associated with protecting or destroying the next unit of an ecosystem) or about the nonlinearities in ecosystem responses to human impact. Often this information is not acquired until after it is too late to reverse harm done (e.g., after heavy flooding). And we still have relatively little experience with institutional mechanisms for safeguarding ecosystem services: these will vary with the different ecological and economic characteristics of the services (such as whether they are public or private goods, the time period and spatial scale over which benefits are realized, and so on).

Further development of case studies addressing these issues would be most helpful. Such work would define the envelope of opportunities and limitations in applying this conceptual framework; it would illumi-
nate how general are the findings from specific locali-
ties; and it would serve as a guide to policy develop-
ment. In the New York City case, for instance, officials
are purchasing land and changing agricultural and mu-
nicipal practices in the hopes of restoring the natural
water purification services of the Catskills—all with
quite limited scientific information. In this particular
case, and generally, success in the policy arena hinges
on whether the scientific underpinnings of policies
are sound.

ECOTOXICOLOGY CAN BE DEFINED as “the study of harmful effects of chemicals upon ecosystems.” This implies that ecotoxicology is not concerned with the detection of chemicals per se, but that it deals with biological effects of (toxic) chemicals that contaminate (or have contaminated) the environment. Biological effects induced by chemicals can be anything from a molecular effect (e.g., genetic change) in an individual organism to effects on the biosphere as a whole.

I. INTRODUCTION

The manifest principles of ecotoxicology involve the application of the principles of toxicology to the environment: focused on human activity leading to the release of molecules such as polynuclear aromatic hydrocarbons (PAH), polychlorinated biphenyls (PCBs), xenoestrogens (XEs), chlorofluorocarbons (CFCs), pes-
...ticides, heavy metals, radionuclides, greenhouse gases (CO_2, CH_4), sulfur dioxide (SO_2) and oxides of nitrogen (NO_x) into the environment. Biomonitoring is undertaken sometimes as the "prelude to remediation." Remediation aims to remove potential toxic substances from a contaminated site, thus restoring ecosystem function as far as is reasonably possible following the removal of the ecotoxicity by biological, physical, or chemical means.

Molecular toxicology is the branch of toxicology (the study of the effects of manifestly poisonous substances on individuals) that adopts the biochemical approach to the understanding of the detrimental threats to life, often recognized by a range of morbid conditions in a variety of fauna and flora. Such pathology can be understood at a molecular level in terms of biomolecular damage undergone by such macromolecules as DNA (deoxyribonucleic acid: the genetic determinant mainly residing in the nucleus of the living cell), RNA (ribonucleic acid: responsible for transfer of the genetic message inherent in DNA structure sequence to the cytoplasm of the cell), and diverse proteins constructed from a choice of sequence of residues of 20 amino acids (obtained mainly from dietary protein hydrolysis during digestion).

It is the increased understanding of chemistry and its associated biochemistry that allows a meaningful prediction of toxicity of chemicals in all forms of life (ranging from bacteria and higher fungi to plants and animals including Homo sapiens). Although no meaningful distinction can be made between natural and manmade chemicals released into the environment, detoxifying enzymes such as the ubiquitous oxygen-requiring enzyme family, cytochromes P-450, present in most forms of life, are useful biomarkers for constitutive or acquired tolerance to chemicals such as polycyclic aromatic hydrocarbons (PAHs), polycyclic halogenated biphenyls (PCBs), and xenoestrogens (XE). In the course of millions of years of biological evolution of species, survivors now display a range of such biochemical defenses against toxins including the more recent pollutants released through industrial activity in processing and manufacturing industries. Particular concern has been displayed recently for the contamination of the environment with endocrine disruptors (environmental hormones). These mimic the biochemistry of natural estrogens (such as 17β-estradiol) and these have been associated with feminization of males, leading to displayed hermaphroditism in a few cases, in polluted environments. Some of these endocrine disruptors are derived from the release of industrial chemicals and are therefore referred to as xenestrogens (foreign-compound estrogens). This is using the accepted nomenclature of xenobiotics as "foreign" or "manmade" chemicals, as contrasted with natural chemicals of which the environment, the diet, and all life is composed.

Several important concepts have been incorporated into the principles of ecotoxicology. For example, "hazardous chemicals" have the potential for causing harm to a variety of organisms; but the assessment of the risk to the biosphere posed by these chemicals must be based on consideration of the exposure (dose) to individuals, populations and communities as well as direct toxicity to the different species involved. Environmental exposure is not only determined by the quantity of a chemical released but depends also on the characteristics of a particular environment and the distribution of the biota in that environment. Soil that contains large quantities of clay minerals and humic substances might lead to immobilization of hazardous chemicals through absorption, while chemicals released in aquatic environments might be dispersed rapidly. In both cases, toxicity to the biota living in these environments might be limited as exposure (bioavailability) is small. Also the distribution of different species in the environment is not random, but populations of a particular species are concentrated at particular sites (niche). For example, in soil some species are found in the litter that lays on the soil surface (epigeic and hemigeic species), while others frequent the deeper mineral soil layers (eudaphic species). It is clear that epigeic and hemigeic species are more likely to be affected by toxic chemicals that enter the soil environment from above than eudaphic species. Besides distribution, exposure will be determined by feeding patterns. Organisms that feed on prey that is likely to have accumulated the substance will be exposed to larger quantities of the toxicant than those that feed on substances that are relatively uncontaminated. Especially recalcitrant, low water soluble chemicals such as PCBs and organochlorines (DDT, for example) can be biomagnified in the environment to lethal concentrations higher up the food chain. Furthermore, toxicity of each hazardous chemical should be related to the metabolism of each major species present, as affected by the toxicant. Therefore, signs of toxicity need to be sought by a battery of methods before meaningful conclusions can be drawn on the environmental risk of a potential chemical released in the environment; environmental pollutants at a specified dose may cause changes in finely balanced ecosystems due to differential toxicity to different species and differential exposure of different species that inhabit the environment.

Much of ecotoxicology relates to the toxic effects of...
chemicals in natural ecosystems, but it must be remem-
bered that man is an integral part of these ecosystems
and effects on the other biotic components of the eco-
systems of which he is part can affect him directly or
indirectly. For example, in relation to bioaccumulation
of toxic chemicals, substances like PCBs, chlorinated
organopesticides, and heavy metals, are likely to accu-
mulate (and cause toxic effects) in the human body
because of the simple fact that man is high up in the food
chain. Indirectly, man is dependent on the biosphere for
the maintenance of the climate, purification of water
and air, and the provision of a sustained food supply.
Disruption of biological activity that impairs the capac-
ity of the living world to fulfill these functions will
ultimately affect humankind’s well-being and survival.
In this respect, therefore, human toxicology and ecotox-
icology are of necessity closely interlinked.

II. APPLICATION OF DIFFERENT
SCIENTIFIC DISCIPLINES
TO ECOTOXICOLOGY

A. Chemistry
Many different xenotoxicants of many chemical struc-
tures are now ubiquitous in aquatic, terrestrial, and
atmospheric environments. Most, however, are present
at extremely low concentration. For example, there may
be 60,000 molecular-species of “hormone-disrupters”
such as the xenoestrogens that may be detected (albeit
by remarkably sensitive detector systems that can re-
spond to even a few hundred molecules for a positive
identification). Nevertheless, most of these xenoestro-
gens are extremely weak molecular-mimics of human
estrogens, and many of these can, paradoxically, stop
the estrogenic response of particular target tissues.
Proposed chemical approaches to ecotoxicology are
often analytical in nature and seek to quantify the effect
of each chemical species that can be identified and
assayed so as to define the concentration-dependence
of any hazardous substance and its consequent environ-
mental or human risk. Quick tests for biohazards are
essential, such as that achieved in the famous Ames
Test for mutagenicity (and related carcinogenicity) in
selected bacteria, for example, by the polycyclic hy-
drocarbon, benzo(a)pyrene. Such mutagenicity (novel
growth-behavior) due to genetic (DNA) damage may
manifest as cancer in mammalian organs (because of
loss of growth-control in particular tissues, due to subtle
alterations in regulation of cellular growth by particu-
lar genes).

B. Biochemistry
Biochemistry studies the chemical processes that take
place in living organisms. The main pertinent principle
of biochemistry that can be applied to ecotoxicology is
the modern concept of enzyme (biocatalytic proteins)
regulation by molecular-intermediates of tissue metabo-
lism in cells. Many xenobiotics (foreign chemicals un-
usual in nature) can interfere with the finely balanced
biochemical reactions of living cells by perturbation of
the web of molecular interactions necessary for life.
Additional problems are due to the molecular dam-
age to DNA (deoxyribonucleic acid) and its related RNA
(ribonucleic acid) along with cellular membranes
(photophosphides that are readily destroyed by reactive
oxygen species (ROS), generated by reactions of these
chemicals with atmospheric molecular-oxygen). The
ecotoxicity of ROS may, however, be ameliorated by
antioxidants in the environment (and by dietary antiox-
idants such as vitamins C, E, A, and D as well as phytoest-
rogen in the diet).

C. Microbiology
The activity of microorganisms is at the basis for most
functions on which life on this planet depends. Due to
their almost limitless metabolic capacities, microbial
communities are responsible for the transformation and
recycling of organic and inorganic molecules in the
environment. This activity results in the maintenance
of nutrient cycles, the maintenance of soil fertility, and
the detoxification of toxic substances in the environ-
ment. Furthermore, many microorganisms are inti-
mately associated with every conceivable higher life
form on this earth. They perform functions without
which higher organisms could not function. Examples
of this kind are organelles that have a microbial origin,
including mitochondria, which are responsible for the
energy generation in eukaryotic organisms (organisms
with a true nucleus), and chlorophyll that allows algae
and higher plants to convert carbon dioxide into sugars
via photosynthesis. Other symbiotic interactions be-
tween microorganisms and plants that are of crucial
importance for plant growth and nutrition are dinitro-
gen fixing microorganisms and mycorrhizae, which
have close associations with the roots of many plant
species. In fact plant roots have adapted specially to
accommodate for these microorganisms. Furthermore,
microorganisms associated with the gut of animals pro-
vide essential vitamins that animals cannot synthesize
themselves. On the negative side, microorganisms are
responsible for causing a wide variety of diseases in
plants and animals. Although this is negative from the viewpoint of the organism (or population) that is affected, disease causing organisms are important in ensuring that excessive population growth of particular populations is curtailed, thus ensuring the maintenance of an environment that contains a rich diversity of species. The interdependence between microorganisms and higher life forms means that toxic effects that affect either group of organisms can have important consequences for the other.

D. Biotechnology

Biotechnology is an applied science that aims to harness different life forms for the benefit of man. Agriculture, antibiotic production, and bioremediation are examples of such applications. Recent advances in molecular biology have given biotechnologists new tools to change the nature of life by genetic modification. This technology has resulted in the creation of organisms that would very unlikely have arisen in nature via normal mating and exchange of genetic material. It is now possible for humans to combine the genes of widely different organisms into one organism, giving this recombinant organism the means to express novel characteristics. Such “novel characteristics” include resistance to diseases and pests, resistance to pesticides, or the means to produce products that are of commercial or medical value. Whereas these organisms are of potential value to society, it is necessary to evaluate their environmental impact before they can be safely released into the environment. Therefore, with the advance of biological science comes the responsibility for biotechnologists to ensure that the integrity of the environment is maintained by ensuring that the biological functions that allow life on this planet to thrive are not impaired. Interestingly, recombinant technology has also opened the way to construct organisms that can be used to monitor the environmental impact of toxicants more sensitively. An important interface of ecotoxicology with biotechnology arises in the use of such genetically modified organisms as biomonitoring tools. However, the detection (and assay) of ecotoxics can be achieved by a variety of methods. An interesting example is the detection of carbon monoxide. This can be achieved using a caged canary (that responds sensitively to carbon monoxide in coal mines) or using an enzyme-based detector electrode that functions as a biosensor for this gas. A detailed account of biotechnological techniques for biomonitoring and bioremediation in relation to ecotoxicology can be found in the book by Lynch and Wiseman (1998).

E. Ecology

Ecology is the study of the interactions between organisms and their environment that determine the distribution and abundance of organisms. These interactions can be studied at different levels of biological integration starting from individuals, which are part of populations, which are part of communities, which are part of ecosystems, which are part of the earth’s biosphere. To gain a living from nature, humans have to understand the interactions that determine the abundance and distributions of organisms on which human life depends. This is not only important for the harvest of species from natural ecosystems by hunting, fishing, and or gathering of plant products, but also where the aim is to modify the natural environment to yield predominantly products that are of economical value as is the case in agriculture and forestry. Not only do we need to understand how we can most efficiently use the environment, but also increasingly we need to be aware of the impact of human activities on ecosystem function in general. Pollution of the environment by human activities (manufacturing, mining, waste disposal, transport, energy use, pesticide use, etc.) can have a large impact on ecosystem function via effects at all levels of biological integration. Especially since the scale of human activities has increased so dramatically over the past century there is a real danger that human activity interferes significantly with the basic biological processes of sustained life, including our own. Therefore, ecological knowledge applied to ecotoxicology aims to evaluate the consequences of human activity to ecosystem function, especially in relation to pollution caused by human activity.

F. Toxicology

Important principles of toxicology that relate to ecotoxicology include the concepts of extent of exposure, persistence, and distribution of chemicals in the environment. Subsequently predictions can be made on the toxicity of such chemicals to individual organisms or populations. The starting point of such analysis is often the chemical structure of each toxin, which will allow some prediction of the behavior of the chemical in the environment to be made. One of the best examples of this kind is the environmental impact assessment of the insecticide DDT. DDT is almost completely insoluble in water but readily soluble in fat. Furthermore, DDT and its degradation product DDE are highly persistent. Its low solubility means that it is easily dispersed in aquatic environments (in the case of DDT it is found at low
concentrations all over the globe) and only accumulates in places with a high fat content (i.e., living organisms). Once it has entered living organisms, it persists and accumulates in the fat tissues of organisms that are higher up the food chain resulting in toxicity. For this reason, populations of both fish eating birds and bird eating raptors such as peregrines and hawks were badly affected by DDT, even in cases where they inhabited pristine environments.

Another aspect of toxicology is risk analysis. This quantitative topic is most easily studied when death rates within a population can be quoted. Whereas the rates can be determined experimentally for animals, plants, and microorganisms, the determination of the effects on the human population is inevitably more difficult to determine, and one of the few situations where effects are well known is the mutagenic effects of radionucleotides, resulting from contamination caused by accidents at nuclear power installations or nuclear warfare.

III. ENTRY, MOVEMENT, AND FATE OF POLLUTANTS IN ECOSYSTEMS

Organic and metallic (including radionucleide) toxicants that enter the environment are regarded as pollutants of air, soil, and water. Their movement and transport is through air and water depending on their volatility and solubility, respectively. Soil and the detritus of sediments provide important solid supports for adsorption to regulate the movement and flow of the pollutants through terrestrial ecosystems, as well as influencing the localization and persistence of the pollutants in the environment. In this respect clay and humus particles that are electrostatically charged have an important role to play. Some organisms will take up the pollutant and concentrate them in their cells, a phenomenon known as bioaccumulation or biomagnification. This is particularly serious where the toxicant enters the food chain leading to progressive accumulation of toxic molecules higher up the chain, including humans. This is often the case with molecules that are relatively biologically inert such as heavy metals, PCBs, and organochlorine insecticides. Accumulation of such molecules in different species can lead to toxicity expressed as reduced growth, reduced fecundity, changes in behavior, susceptibility to diseases, or increased mortality. However, on the positive side, where there is storage of the pollutant in the cell, as is normally the situation with (heavy) metals, it is possible that the pollutant might be harvested and therefore removed from the environment. This especially applies to plants that hyper accumulate metals in their tissues. The application of this process for the cleanup of contaminated land is known of phytoremediation. Also, many pollutants are biologically degradable and can therefore be detoxified. Both plants and mammals have a range of enzymes that are involved in detoxification of molecules that are potentially harmful to them (cytochromes P-450, for example), whereas the almost limitless metabolic capacity of a wide variety of microorganisms allows degradation of pollutants, especially hydrocarbons, into nontoxic molecules such as water and carbon dioxide. The stimulation of microbial degradation and metabolism of pollutants is known as bioremediation and is currently used to clean up contaminated land while microbial degradation of pollutants present in sewage and water is used in a variety of water purification systems. The fate of pollutants in the environment is therefore not only dependent on the molecular characteristics of the pollutant but also on a range of biotic and abiotic factors.

IV. BIOMONITORING

The ultimate goal of biomonitoring is to use biological effects resulting from chemical exposure for making predictions and deductions about the quality of the environment for life in general and human life in particular. Biomonitoring activities can be conducted on various levels of biological integration, over a period of time. Several overlapping terms are commonly used in this process. It is worth noting that some of the tools are, strictly speaking, alternatives for chemical/physical methods to measure bioavailability of chemicals in the environment. In other words, they do not provide information on ecological effects per se.

• The term bioreporter is used for a molecular tool, often genetically modified cells, to transform the presence of a chemical into an easy measurable signal (e.g., luminescence).
• The measurement of biochemical and physiological variables in individuals or in their excretion products, providing information on exposure or damage, is indicated by the term biomarker.
• A biosensor or bioprobe is a physical device that allows the detection of a chemical as an electrical signal derived from a biocatalyst, such as an enzyme or an antibody.
• A bioassay is a toxicological test system in which

the activity of a chemical is measured as an adverse effect on a population of a specific test species. A bioindicator is used to detect the effects of chemicals at the individual, population, community, or even ecosystem level.

Important in this respect is that when we move up to the higher levels of biological integration (populations, communities, ecosystems), effects are increasingly difficult to link to a specific chemical, even though the effects measured are of more importance. Furthermore, it takes an increasingly long time for higher levels of integration to respond to a chemical insult. For example, DDT took years to bioaccumulate up the food chain resulting in negative effects at the population/community level. On the other hand, chemicals that are apparently nontoxic at the lower levels of biological integration (carbon dioxide, chlorofluorocarbons (CFCs), sulfur dioxide, etc.) can have profound effects on all levels of biological integration. These chemicals might not directly affect biological processes but affect the chemical balance of the earth's biosphere (air, water, and soil). For example, greenhouse gases (carbon dioxide, methane, and water vapor) trap the sun's long wave radiation augmenting global warming, which could lead to profound changes of the world's ecosystems. CFCs contribute to the destruction of the earth's protective ozone layer, leading to an increase in harmful UV radiation that reaches the earth, resulting in increased lethal mutation rates and cancer. Sulfur dioxide and NOx emissions lead to acid rain and acidification of soil and water, which in turn leads to the release of toxic quantities of metal ions in soil and water that kill both vegetation and animal life. An interesting example of this kind is the acidification of lakes in Scandinavian countries as a result of acid rain. The resulting lower pH of the lake water means that the water can contain a higher concentration of aluminum ions. However, the pH around the gills of fish is slightly alkaline, resulting in the precipitation of aluminum on the gills. This results in the impairment of gill function and suffocation of the fish. Even though Scandinavian lakes affected in this way look perfectly clean, they are devoid of fish.

A variety of specific tests have been employed to investigate the effects of chemicals on the environment. Generally the bionic effects used for biomonitoring deploy biota from the environment and expose them to different concentrations of the test chemical. Mortality of fishes, for example, has been used to assess toxicity of chemicals that are used in the soil environment (Table I). In the soil environments a variety of effects can be investigated as to whether the retention capacity of soil would affect the toxicity of a chemical leading to leaching into groundwater or the living space for plant production and soil communities. In this respect, the assays relate to the effects on populations, gene products (enzymes and metabolites), or impacts (plant bioassays) (Fig. 1). However, the exciting development of...
recent years is the recognition that these effects are all controlled by genes and another method of biomonitoring is to use gene (DNA) probes (Fig. 2). This option is very much in its early stages and the concept is to link a gene, which responds to a specific chemical or general effect, to a promoter DNA sequence and a reporter DNA sequence that either encodes for an enzymatic effect or any other specific signal. It is therefore possible to use genes, which respond to mutagenic substances with a light signal that is proportional to its mutagenic potential in the environment. Whereas this approach offers much promise, the reality is that it is complementary to the other methods currently deployed and should be used in conjunction with them.

A particular useful activity, which has been monitored in aquatic environments, is cytochrome P450. (Table II). This is the terminal component of the mixed-function oxygenase, which catalyses exopoxidation, hydroxylation, dealkylation, and desulfuration, all critical in detoxification of toxic molecules in invertebrates and vertebrates (including humans). To date, more than 750 cytochrome P450 genes have been identified (Nelson, 1998). The cytochrome P450/1A (CYP1A) isozyme is a biotransformation enzyme involved in a wide range of xenobiotic metabolisms (chemicals foreign to the natural environment) including metabolism of polycyclic aromatic hydrocarbons (PAHs). Usually CYP1A has been used as a biomarker in fish and mollusks. The linking of this enzymatic function with its genetic control offers a great deal of potential for the biomonitoring of toxicology of both marine and freshwater ecosystems.

### V. BIOLOGICAL PROCESSES

The question can be raised why it is necessary to analyze complicated biological processes if the chemical in question can be measured directly using chemical or physical methodologies. There are at least three situations where biomonitoring provides answers that cannot be arrived at using direct chemical measurements. The first use for biomonitoring is in situations where one wants to trace the chemical history of an environment. For example, the pH history of lakes can be deduced from the percentage acidophilous and alkalophilous species within the diatom communities preserved in sediment cores (Renberg and Hellberg, 1982). Similarly, pollen records preserved in soil provide information on past vegetation from which the past environmental conditions can be deduced. The second use of biomonitoring is a situation where the activity of a chemical is short-lived but the effects are persistent. For example, pesticides that disperse rapidly or are broken down rapidly cannot be measured easily, but their biological effects might persist for long periods. The insecticide deltamethrin is active only for a few hours after spraying, while effects on sensitive ground spiders and beetle fauna remain visible for weeks after spraying (Evers, et al., 1989; Jagers op Akkerhuis, 1993). The third reason, and probably the most important one, for using biomonitoring is that effects of chemicals are dependent on the interactions that take place within the environment itself after their release. These interactions can be of a physical/chemical nature where...
the chemical is immobilized on to soil particles and is therefore not bioavailable. For example, the toxicity of metals, such as copper and zinc, in soil is determined by their bioavailability in soil. Both copper and zinc ions bind to soil minerals (mainly clay particles) and humic substances and as such are unavailable to the biota present in soil. Soils contain large quantities of these potential binding sites and therefore toxic effects of heavy metals are often buffered, even at relatively high concentrations. Because of this soil-buffering capacity, it usually takes some time of sustained metal inputs before metal ions become bioavailable at concentrations that are toxic. Both the mineral and organic fractions of soil interact with metal ions, providing negatively charged surfaces on to which cations can bind. Such adsorption displaces the cation that was previously counter-balancing the colloid's negative charge, hence the ability of colloids to adsorb ions in this way is known as the soil's cation exchange capacity (CEC). Heavy metals may also specifically adsorb on to hydrated oxides of aluminium, iron, and manganese by the formation of partly covalent bonds and can be chelated by solid-phase humic substances or by other organic ligands. The adsorption of metal ions is also affected by the soil pH. Acidification decreases the CEC of humic substances when carboxyl and ammonium groups will become protonated, reducing their capacity to bind metal ions. The increase in hydrogen ions will also increase the competition for negative binding sites, leading to the displacement of metal ions. Therefore, the size distribution of mineral particles, the amount of organic matter and the soil pH will to a large degree determine the metal buffering capacity of the soil (Gupta, 1991).

Besides physical/chemical interactions, chemicals interact with the biota present in the soil. For example, sustained use of specific pesticides leads to the development of microbial communities that degrade the pesticide, reducing their half-life time and therefore their environmental impact. On the other hand, chemicals such as PCBs and organochlorides are likely to accumulate up the food chain resulting in high concentrations of residues distant from the point of release, thus increasing their environmental impact. As biological systems are not just collections of independent organisms but are strongly dependent on each other for their survival, it follows that chemical effects on one species can have important consequences for species that depend on the affected species. An example of this type of indirect effect is the decline of the grey partridge (Perdix perdix) in West Sussex, England. It could be shown that 48% of chick mortality was explained by the density of preferred insects. Given that reduced availability of insects is the key to the partridge decline, it was postulated that this might be due to increased pesticide usage, especially since there was a strong correlation between the partridge decline and increased herbicide use. The effect of the herbicides was shown to be indirect (they are relatively nontoxic to partridges), removing the host plants on which the insect larvae fed that were the food source of the partridge chicks, resulting in less insects and therefore less food for the partridge chicks. In conclusion, because biological effects are dependent on the behavior (movement, persistence, bioavailability) of the chemical in the environment, the sensitivity of biota and the role these biota play in ecosystem function, biomonitoring is often the only available way for monitoring chemical effects.

VI. EARLY WARNING SYSTEMS

Life as a whole can be seen as an hierarchical systems with distinct levels of biological integration. Going from a low level of organization to a high level of organization we can recognize cells that make up tissues, that make up organs, that are part of an organism; these organisms are arranged in populations that form part of communities, that are ultimately part of ecosystems. In general, it can be said that biological systems are at each level of organization buffered to resist change in overall performance by adjusting the components that make up that level of integration. The result of these buffering effects is that effects at lower levels of integration are dampened so that they do not affect higher levels of integration. Only when the buffering capacity at a certain level of integration is exceeded will the next level of integration be affected. This implies that toxic effects can be measured at the lower levels of biological integration before they result in effects at higher levels of integration. Because the aim of biomonitoring is “to provide a means by which (impending) changes in ecosystem function can be detected,” compensatory effects at lower levels of integration can provide an early warning system of adverse chemical effects. A good example of such an early warning system is the thinning of bird eggshells as a result of DDE (one of the metabolites of DDT). DDE affects Ca deposition in eggshells (physiological change). However, only when eggshell thinning is in excess of 16% to 18% will this lead to a decrease in breeding success of the birds affected. Eggshell thinning is therefore an early warning system for population change. Not all bird populations are likely to be affected as DDE accumulates up the food chain. Only birds that...
ALA dehydrogenase is only induced by lead, while in-
specific stimulus. For example, inhibition of the enzyme
is meant that a biological effect can be related to a
forms of (chemical) stress. With the term
ent degrees of specificity and sensitivity to different
Within each level of biological integration the biological
are classified shows that we have still a long way to go.
Simple fact that only a fraction of the species that make up “biological life”
are at the top of the food chain (raptors and fish-eating
birds) will be affected in the first instance. However it
can be assumed that if DDT use had continued, the
decline in raptors and fish-eating birds would eventu-
ally have resulted in community changes.

What is important in this context is to recognize
which factors determine the buffering capacity at each
level of biological integration. These factors can be used
profitably in biomonitoring. It is, however, important
to recognize that if we are interested in impending
changes at the community level, it is probably most
sensible to look for changes that are occurring at the
level below (i.e. the population level). Similarly, im-
pending population effects are most profitably investi-
gated using effects on individuals. However, changes
at the organism level will be too sensitive for making
reliable predictions at community level and above. This
simple fact is often overlooked in biomonitoring where
current molecular technology has allowed precise inves-
tigation at the lowest levels of integration. These tech-
niques allow the development of sensing systems that
pick up changes that occur at the molecular and physio-
logical level. Whereas these approaches are valuable for
medical purposes in which we are interested in warning
systems that help prevent problems at the individual
level, they are inappropriate for monitoring ecosystem
changes, in that they are far too sensitive. In choosing
the most appropriate monitoring tool, one has to evalu-
ate its relevance, reliability, robustness, responsiveness,
and reproducibility. These factors, known as the 5 Rs,
will differ according to level of biological integration
and the composition of biological units that make up
that level. It is unlikely that an environmental monitor-
ing system will be “a freeze dried, talking bug on a
stick” (van Straalen, 1998). As interactions that govern
processes at each level of biological integration become
apparent, new and more appropriate biomonitoring
tools will become available. The simple fact that only
VII. SPECIFICITY AND RESOLUTION
Within each level of biological integration the biological
units that make up the level of integration display differ-
ent degrees of specificity and sensitivity to different
forms of (chemical) stress. With the term specificity it
is meant that a biological effect can be related to a
specific stimulus. For example, inhibition of the enzyme
ALA dehydrogenase is only induced by lead, while in-
duction of an immune response might be triggered by
a wide variety of causes. The term resolution is used to
indicate the ability of a bioindicator to respond to small
environmental changes. For example, a specialized
predator at the top of a food chain is a more sensitive
indicator of bioaccumulation of persistent pesticides
than omnivores with a varied diet. Although it seems
that sensitive indicators with a great resolving power
hold the greatest promise for biomonitoring, these
properties are likely to result in overcaution and false
alarms. In general, it can be said that indicators at lower
levels of biological integration are more sensitive than
characteristics that relate to higher levels of biological
integration. Therefore, indicator species are more sensi-
tive than diversity indices, for example. What makes a
“good” bioindicator will depend on the information that
is required. Looking at a “soil ecosystem” for example,
the biological components that make up the system
consist of plants, vertebrates, invertebrates (insects,
earthworms, nematodes, mites and springtails), proto-
zoa, bacteria, and fungi, all of which perform crucial
roles in the maintenance of soil ecosystem function.
When the system is exposed to a potentially toxic chem-
ical the ability of each population to cope with this
exposure will depend on genotypic plasticity within
the population, phenotypic plasticity, mutation rate,
metabolic capacity, and level of exposure. Genotypic
plasticity will be high in microorganisms that multiply
fast and can acquire resistance genes via mutations or
by acquisition of plasmids carrying resistance genes.
As a result, adaptation of microbial communities to
chemical stress is likely to be high. Furthermore, be-
cause of the almost limitless metabolic diversity dis-
played by microorganisms, populations that contribute
to the detoxification of a toxic chemical might increase
rapidly (comparable with the activation of the immune
system as a response to foreign molecules/organisms
that enter a higher organism). Other organisms (plants,
vertebrates, and invertebrates) that have a large pheno-
typic plasticity might respond to a chemical insult by
avoiding those areas that are most contaminated. Fur-
thermore, spatial distribution of the biota in the soil
environment and their mobility will both determine
exposure and therefore toxicity. Only when there is a
clear understanding of “normal” distribution and diver-
sity of the biota in a given ecosystem is it possible to
relate biological patterns to the effects of a toxicant in
a meaningful way.

Because of the biological complexity of ecosystems,
efforts have been made to classify organisms not ac-
cording to species but according to similarities in life
strategy. Biological life can be roughly classified by the
way organisms spend resources on their offspring. Or-

ECOTOXICOLOGY
371
organisms that invest in large numbers of offspring (giving each limited resources) are termed r-strategists, while those species that invest in few offspring (each of which is provided with ample resources) are termed K-strategists. Looking at the spectrum of life, there is a general trend that large organisms are K-strategists, while small ones are r-strategists. Although this is true to a large extent, within a certain body class size there are organisms that have adopted r- or K-type survival strategies. For example, mice are typical r-strategists (they have many large litters each year), while bats produce every two years a single offspring, making them typical K-strategists. Not surprising, K-strategists are characteristic for stable, climax environments while r-strategists are characteristic for unstable pioneer environments. In terms of “stress,” K-strategists are adapted to cope with biological stress (competition, predation, etc.), while r-strategists are adapted to cope with physical/chemical stress but are not good at coping with biological stress. In general, it can therefore be stated that r-strategists are insensitive to chemical stress, while K-strategists are sensitive. When an ecosystem is challenged by toxins (pesticides, for example), the r-strategists (the pest organisms) are the first to develop pesticide resistance, while the K-strategists (nonpest species) will disappear. The reason for this might be found in the fact that large numbers of offspring provide large genetic variability leading to rapid selection of the best-adapted individuals. Chemical/physical stress on an ecosystem will therefore lead to a shift in the balance between r- and K-strategists in favor of r-strategists. This principle has been used successfully to monitor environmental pollution and disturbance using colonizer/persister (c-p) indices applied to nematodes (Bongers, 1990) or perturbations of rhizosphere microbial communities (De Leij et al., 1993).

Another useful way of looking at communities and ecosystems is by classifying the organisms that inhabit that ecosystem by their “trophic function.” Using this approach, organisms can be classified (aboveground) as primary producers (plants and algae), herbivores, predators, and top predators, while organisms that feed on a variety of food sources are classified as omnivores. In general, food chains have no more than four trophic levels because less and less energy is available higher up the food chain. Furthermore, dependence of predators and top predators on exclusive feeding sources make them vulnerable to perturbations lower down the food chain. Using the concept of trophic levels, it can be argued that specialized feeders are more sensitive to environmental stress (when this stress affects their food source) than organisms that are less specialized. Not surprisingly, when recalcitrant chemicals enter the food chain it is the specialized feeders (for example, peregrines and sparrow hawks that feed exclusively on birds) that are the first to be affected by toxins. Beside the fact that they are exposed to relatively high levels of a pollutant, these organisms are often very skillful specialized hunters. Any impairment of these skills due to a toxin will result in starvation. Therefore, these species can be sensitive bioindicators of toxins, even at sublethal concentrations.

Another important ecological concept that can be used to simplify ecosystems in a meaningful way is the concept of keystone species. The idea is that even though there is dependency between all species that are involved in a certain food web, some species are more important than others. It is important in this context to make a distinction between dominant species that derive their importance to the ecosystem in terms of biomass or energy flow and keystone species. Keystone species are often relatively rare but have a major impact because of their key regulatory function in the system as a whole. This is because these species are involved in more links or interact with parts of the ecosystem that maintain living conditions for a wide variety of other species. In other words, the species diversity of an ecosystem is determined in large part by a few keystone species on which many others depend. A detrimental effect on these species will result in the collapse of the whole ecosystem (or at least a large part thereof). Several different categories of keystone species have been recognized, such as keystone predators, keystone prey, and keystone habitat modifiers. One of the best-studied examples of the importance of keystone predators is the starfish (Pisaster) and predatory whelks (Nacella) in pools along the rocky intertidal zone. Removal of these predators led to the disappearance of 80% of the prey species and the nearly complete dominance of the prey community by mussels (Mytilus). Sea otters (Enhydra lutris) have also been labeled as keystone species as they limit the density of sea urchins, which, in turn, eat kelp and other macro algae that provide the habitat for a large variety of species. Without sea otters the sea urchin population explodes resulting in the destruction of the kelp forests leading to the loss of habitat for those species that depend for their survival on the kelp forests for reproduction, shelter, and food. The way keystone species are affected by toxins is an important consideration in ecotoxicology, because they represent the Achilles’ heel of an ecosystem. Not surprisingly, keystone species such as earthworms and honeybees are often used in toxicity testing because they are important for ecosystem function in general.
Clearly a negative effect on ecosystem function is often due to alterations of complex interactions within the ecosystem itself. In most cases, toxic effects are buffered due to the compensating capacity of an ecosystem. However, occasionally toxic effects can affect species that are responsible for essential functions in that ecosystem. Further insight in the way that different species contribute to ecosystem function is an essential requirement for the development of the most appropriate biomonitoring tools for assessing the ecotoxicological effects of chemicals.

VIII. CONCLUSION

Currently there is growing concern internationally about environmental toxicants affecting biodiversity and human health. Biodiversity has come to the fore by the United Nations meetings; the first of which was in Rio de Janeiro in 1992. The medical profession is increasingly concerned about a range of conditions that might be induced by chemicals in the environment. This is resulting in moves to increase legislation. The study of ecotoxicology seems therefore certain to grow in importance, as well as there being a stimulus to prevent problems occurring in the first place via the development of clean technology and stimulation of sustainable land use. On the other hand, ecotoxicology can help to identify existing pollution problems, which in many cases can be cleaned up using a variety of remediation strategies.

EDIBLE PLANTS

I. Food Habits
II. The Diversity of Food Plants
III. Geographic Patterns of Food Plants
IV. Are Edible Weeds, Weeds?

GLOSSARY

cultivar Cultivated variety or genetic strain of a domesticated food plant.
domesticate Plant that has been selected by humans and adapted for use as a food crop, nutrient, fiber, or other purpose.
ethnobotany Study of the variety, natural history, and characteristics of the plants used by human cultures.

THE VARIETY OF PLANTS NORMALLY CONSUMED BY HUMANS represents a tiny proportion of what nature supplies. Of the estimated 270,000 plant species recognized in the world, about 12,500 species from over 3000 genera are considered edible to humans.

I. FOOD HABITS

Animals, being terrestrial or marine, have limitations with respect to the variety of species they consume. They depend on what nature offers in the place where each animal lives. Since the geographic ranges of species are relatively widespread, the individuals of a given animal species may vary their food resources in different sites of the range, according to their opportunities. For this reason, the variety of plants ingested by a given species is always greater than the variety of plants ingested by an individual or by an entire population.

Domestic as well as wild herbivores may eat a wide variety of food items, but they have clear preferences for particular plant species. Some ungulates are capable of selecting the most nutritious individual plants among those of the same species. They select forage mainly by smell, and secondarily by taste. Volatile substances in the plants may either inhibit or attract foragers, and are largely responsible for their palatability. According to Klein (1970), the nutritive value of plants available to wild ruminants depends on the stage of maturity of the vegetation, with highest nutritive quality coinciding with the initiation of growth, as well as with soil type and climate. Rapid growth in plants is correlated with high nutritive quality. Similar conclusions were reported by Gardarsson and Moss (1970) in a study of food selection by the Icelandic ptarmigan (Lagopus mutus). This bird consumed leaves and flowers of 8, 11, 10, and 11 species, respectively, in summer, autumn, winter, and spring.

Similarly, the European hare (Lepus europaeus) in northwestern Patagonia makes use of 17 to 21 species of plants in a given season out of a total of 26 species that it consumes over the year. Table I provides a short sample of the variety of food consumed by different

</table>

herbivorous and omnivorous mammals. The case of the Soay sheep was included to show how a domestic herbivore may restrict its diet in a species-poor environment. Of course, the range of foods ingested by other animals may vary widely. Monophagous insects restrict themselves to only one plant species, soil amoebae (Acanthamoeba) normally ingest five species of microscopic algae (Heal and Felton, 1970), and polyphagous, pest arthropods may feed on more than 300 species of crops and wild plants. The number of food plants eaten by humans is not far from the figures shown in Table I.

Domestic and wild ungulates may show a copious range of food species but they focus on a few, preferred plants. A number of less palatable species are used only in time of food scarcity. Studies performed in western Argentina by M. B. Kufner and S. Monge showed that the rodent Lagostomus maximus increases the variety of its food sources in degraded habitats and during droughts.

A. Standards of Consumption

On an individual basis, people use a small number of plant items per day, perhaps between 10 and 20 species or products. A normal diet includes common vegetables, fruits, seeds (in the form of flour or oil), roots, sugar, beverages (beer, wine, colas), condiments, teas, and herbas. The number of plant species normally used by an individual over a year, however, is about 100, although this is limited by the number of edible plant items commonly offered by popular markets and supermarkets. Taking into account all the variety of greens, vegetables, fruits, grains, nuts, and condiments in an exceptionally well-provisioned supermarket, the figure (including different varieties and brands) may rise to 600 according to Duke (1992).

The stomach contents of two mummies that were found well-preserved in Danish bogs provided interesting information about the gastronomic habits of people during the Iron Age. Their last meals contained 66 different plant taxa (Godwin, 1960; King, 1966), many of which are nowadays considered as cosmopolitan weeds. Before the invention of agriculture, in the Paleolithic Age, humans were hunter-gatherers, and probably had a better knowledge of the variety of edible wild plants than modern people. This knowledge, however, has slowly been lost since the Neolithic and, in present times, is still lost after one or two generations of acculturation in aboriginal communities (Plotkin, 1993). The process of “civilization” goes hand in hand with the loss of knowledge, as well as with the abandonment of traditional crop varieties and the habit of gathering wild plants. But at the same time, new cultivars, coming from distant countries, are constantly increasing the variety of foods. A recent case is that of the kiwi fruit (Actinidia delicosa), which originated in China and then was renamed, cultivated, and popularized in New Zealand. The roots of the ahipa (Pachyrhizus ahipa) and jicama (P. erosus), of Central American origin, have become increasingly popular in the United States and Southeast Asia, especially the latter species, which has a similar texture and flavor to the bamboo shoots and is used by Asian food restaurants in Western countries (National Research Council, 1989; Brücher, 1989). Rice
(Oryza sativa), of Asian origin, is at present the most popular staple in warm countries of South America, while the South American potato (Solanum tuberosum) has become "mandatory" in the European cuisine.

II. THE DIVERSITY OF FOOD PLANTS

No one has compiled a complete record of edible plants for the entire world. The Food and Agriculture Organization (FAO), part of the United Nations, publishes an annual report of the production of the commercially most important foods. This list includes about a hundred species of plants. In The Oxford Book of Food Plants (Nicholson et al., 1969), the number increases to 389 species distributed among 81 plant families. These are both locally and widely known cultivated plants. Duke (1992) estimated that North American Indians ate 1112 plant species. This figure is set at 1886 species according to Moerman (1998). More than 3000 edible species are carefully listed and commented on in the voluminous book Cornucopia, compiled by Facciola (1990), but in its preface Noel D. Vietmeyer suggests that there are about 20,000 edible species across the world. Probably, the most complete inventory is Kunkel's (1984) book, which lists roughly 12,560 species from 3100 genera belonging to about 400 families of flowering plants and ferns. This list, however, is being constantly enriched by the contribution of many ethnobotanical studies.

The proportion of edible plant species in slightly disturbed communities is variable. In the Sonoran Desert it is about 15%. Oma Indians from Tierra del Fuego made use of at least 6% of this island flora, whereas the Cháechebo Indians, in the Bolivian Amazon, use 21% of their surrounding flora. Medium to highly disturbed communities may contain similar or higher proportions of edible species for human consumption. For example, in western Uruguay the proportion is 17%, in southwestern Córdoba province (Argentina) it is 19%, in the outskirts of Havana (Cuba) it is 33%, in swidden (slash-and-burn) fields of northern India it is 43%, and in experimental fields in Saskatchewan (Canada) it may reach 63% of all wild plants. Yet studies like these do not necessarily reveal the actual possibilities offered by nature, but rather the knowledge of informants and/or the perspicacity, experience, and field-work time employed by the investigators. According to the estimate that about 10% of any flora represents food resources, then 10%, or 27,000, of the 270,000 species of plants already recognized by world botanists should be edible.

Since historical times, because of written testimony, Europe has conserved people's knowledge of gastronomic matters. From the botanical point of view, the United Kingdom is probably the best-known country in the world. If we compare the floristic list compiled by Martin in 1976 with Kunkel's list of food plants, and discard the exotic species, hybrids, and other sub-specific taxa, as well as plants used only during famine times, we can verify that out of 1503 species considered, 350 are edible. In other words, 23% of the British flora is edible. Thus, we have two estimates of the possible richness of edible vascular plants—10 and 23%—and they represent between 27,000 and 62,000 species, respectively, based on the 270,000 known at present. Because the description of the world flora has not been completed yet, the final list of comestibles will probably increase in the future.

By comparison, less than 2% of the Central American flora is edible, based on the list prepared by Duke (1992). Possible explanations for this remarkable difference are: (1) greater taxonomic ignorance and/or less exploration of the natural resources—because the flora of Central America is much richer than the flora of Britain, humans may have concentrated on fewer, more abundant and profitable plants, and disregarded the less useful ones; and (2) widespread loss of cultural heritage and environmental knowledge following the conquest and colonization by European countries.

A. The Most Prolific Taxa

A first, rough estimation at higher taxonomic ranks indicates that the proportions of edible species are quite similar to the proportions of "common" (edible and nonedible species) species present in the plant kingdom. The right-hand column in Table II is based on a random sample of 1790 food plants appearing in Kunkel (1984). If the property of being edible or palatable were

</table>
randomly distributed among the different taxa, then it would be predictable that the most numerous families of plants would contain a higher number of edible species than from common species. Among families with the lowest ratios are the Asclepiadaceae (8.0), Cruciferae (8.6), and Rutaceae (10.0). Families that are richer in species per genus are the Begoniaceae (295.0), Aizoaceae (208.3), and Eriocaulaceae (92.3), yet they show no evidence of having experienced a process of selection, that is, of "proclivity" or "rejection" by humans, that would have led them to speciate toward palatability or distastefulness.

Of the 389 more frequently cultivated species considered by Nicholson et al. (1969), the ranking goes as follows: Rosaceae (13.3% of total species), Leguminosae (8.5%), Compositae (5.9%), Umbelliferae (5.4%), and Cruciferae (5.1%). They are followed by Palmae, Cucurbitaceae, Rutaceae, Alliaceae, Chenopodiaceae, Dioscoreaceae, Annonaceae, Ericaceae, Grossulariaceae, and 66 less prolific families. Kunkel (1984) states that the Rosaceae is the richest family among food plants. The analysis of a sample of 6222 items from his list confirms this assessment. Rosaceae appears at the top of the list, comprising 5.8% of the cases. The first 30 families is shown in Table IV.

### Edible Parts

Some plant genera are extremely abundant in edible species and may show particular tendencies toward a given kind of food (Table V). For example, all of the 205 species of *Rubus* appearing in Kunkel’s list provide edible fruits. Among them, there are three species whose leaves are also used as tea. Similarly, the 80 or more...

species of Prunus provide edible fruits, as also occurs with Rosa spp. and Ribes spp. The majority of Piper species are used as black or white pepper or as a spice for curries. Rumex provides 44 species with leaves used as vegetables and 3 species with edible roots. Of the 100 edible species of Solanum, 59 are used only for their fruits, 20 species only for their tubers, 14 for both fruits and leaves, 6 species only for their leaves, and a single species exclusively for its seeds.

An analysis of the data compiled by Duke (1972) for Central America indicates that 85% of the plant species are used for a single purpose, 10% have two uses, 4% have three uses, and 1% have four uses (leaves, flowers, fruits, and seeds). A similar analysis of the 350 edible species of the native British flora yields slightly different proportions: 78%, 19%, <3%, and <1% for one, two, three, and four purposes, respectively. One of the exceptional cases of variability of uses is that of

hops (*Humulus lupulus*). Its leaves, roots, flowers, and bark may be used as food and as condiment. The pumpkin (*Cucurbita moschata*) provides fruits, seeds, flowers, young leaves, and shoots for human consumption.

It is clear from Table VI that some kinds of food are scarcely used, such as bark, flowers, sap, and liquorice. In contrast, leaves (including stems, sprouts, seedlings, and shoots) and fruits seem to be the most preferred food.

### III. GEOGRAPHIC PATTERNS OF FOOD PLANTS

On the basis of a sample of 1790 species from Kunkel's list of food plants, it appears that edible herbs are more numerous than trees, shrubs, and vines. "Vines" include all the climbing, creeping, and epiphytic plants. Table VII shows that in decreasing order of species richness, the Indomalayan regions appear first, followed by the Neotropical, Palearctic, Ethiopian, Nearctic, and Australian (or Australasian) regions. By means of a chi-square test, at a significance level $P < 0.05$, the Nearctic and Australian regions show greater, and the Palearctic lower, proportions of food trees than expected. The proportion of edible shrubs does not vary significantly among regions, although at a $P < 0.1$ the Neotropics seem to have a higher proportion than the rest of the world. The Palearctic region shows a higher and the Neotropics a lower proportion of herbs, while the latter region is richer in vines ($P < 0.05$). In contrast, the Northern Hemispheres (Paelearctic and Nearctic regions) shows a significantly lower proportion of vines than the Southern Hemisphere.

According to biogeographic regions (Table VIII), the Palearctic shows a significantly greater proportion of species that provide edible leaves, stems, and sprouts than the other regions. The Australian region is characterized by a greater proportion of edible seeds, and the Neotropics by its abundance of fruit species. Of course, these differences were derived from the sample analyzed by us. For instance, the appearance of zero values for beverages from the Australian and Palearctic regions does not mean that there are no species of this kind in their florae; they were simply not registered in our sample of 1790 species. On the contrary, the high proportion of edible fruits in the Neotropical region is repeatedly verified in ethnobotanical studies performed in different countries of Central and South America. These contrasts may be attributed to differential characteristics of seed dispersal evolution within their plant communities, as well as to prevailing cultural trends in the use of natural resources. The possibility of ethnobotanists showing biased attention toward particular kinds of food should not be discarded.

### IV. ARE EDIBLE WEEDS, WEEDS?

The habit of gathering wild food plants has not been totally lost. E. R. Spencer maintained that "any plant is a weed if it insists upon growing where the husbandman wants another plant to grow. It is a plant out of place in the eye of man; in the nice eye of nature it is very much in place." Many of our dearest crops, however, have originated from weeds. In the course of time, humans learned how to profit from them. Oats (*Avena sativa*), foxtail millet (*Setaria italica* derived from *S. viridis*), chicory (*Cichorium intybus*), pak choi (*Brassica rapa*), spinach beet (*Beta vulgaris*), and many more

species appeared originally as invaders in ancient cultivated fields. Furthermore, several cosmopolitan “weeds,” such as dandelion (*Taraxacum officinale*), garden rocket (*Eruca vesicaria*), common purslane (*Portulaca oleracea*), and shepherd’s purse (*Capsella bursa-pastoris*), are nowadays cultivated for the specialty food market.

After analyzing a set of 22,521 species of plants inhabiting natural ecosystems of North and South America, we concluded that 11.3% were edible. In another sample of 1269 species from seminatural communities in the temperate Neotropical region, edibles were 20.3% of the total. But if only weeds are considered (2455 widely spread species), the proportion mounts to 35.6%. This demonstrates that the degree of environmental disturbance correlates with the proportion of weeds, which in turn increases the proportion of edible food resources. This should not be surprising given that 16 of the world’s 18 most aggressive weeds provide parts for human consumption. Because weeds are so numerous (more than 10,000 species catalogued) and so abundant (averaging 1.3 and 2.1 tons/ha in a temperate and a tropical area of northwestern Patagonia and eastern Mexico, respectively. Diaz-Betancourt et al., 1999, Rapoport et al., 1998), they stand ambiguously as both enemies and potential benefactors of humanity.

The prospects for the future of food plant diversity appear to be auspicious. Further research should be conducted to manage and profit from these varied and abundant natural resources. At present, more than 15,000 species of food plants are recorded and this figure is constantly growing. Yet most of the world is fed with about 20 crops. As has been pointed out by Facciola (1990), 8000 cultivars of apples have been developed by humans, but only a handful are available in supermarkets.

GLOSSARY

formal education Education that takes place in a school environment.
informal education Education that takes place in non-school settings, such as museums, zoos, parks, or through the media.
out of school experiences Things that individuals experience that may support or reinforce learning. These might include participation in youth-serving organizations or hobbies such as bird watching.

THIS CHAPTER REFLECTS a view from the science education and scientific communities of what all high school graduates would know and understand about biodiversity. This is a statement of learning goals and does not necessarily represent the actual understandings that an average student would attain through study of science through grade 12 in the typical American high school.

1. INTRODUCTION

The Convention on Biological Diversity articulates a case for nations of the world to come together to undertake activities to improve conservation of biodiversity and sustainable use of biological resources. As of June 1997 more than 170 nations had ratified the convention. In addition to calls for better management, more research, and study and international and regional cooperation, there was also recognition of the role of education, public participation, public information, and the development of a cadre of professionals to support the goals of the convention.

A recent report to President Clinton from the President's Committee of Advisors on Science and Technology (PCAST) makes recommendations to strengthen "the understanding and management of biological resources" (PCAST, 1998). Among the recommendations in Teaming with Life: Investing in Science to Understand and Use America's Living Capital are calls for increased opportunities for formal and informal education centered on biodiversity and ecosystems, for interactions between scientists and students, and for continuing professional education for K–12 teachers.

This chapter will outline aspects of formal and informal education focused on biodiversity. Specifically, it will outline learning goals around biodiversity for K–12.
education, recommended school-based experiences that can lead to an attainment of these goals, and evidence as to the extent to which these understandings are being achieved by students. The chapter will review school-based environmental education initiatives and describe how these compare to and differ from education about biodiversity. The chapter will then continue with a discussion of informal learning opportunities in "places of science" as well as those available through youth-serving organizations, tourism, and field experiences. The section on general education will conclude with information on public interest in and awareness of biodiversity.

A brief section will discuss biodiversity and tertiary education: biodiversity themes and courses as part of liberal education as well as issues in the education of professionals and specialists who work in biodiversity research, management, and conservation.

II. LEARNING ABOUT BIODIVERSITY: K–12 EDUCATION

How do students learn about biodiversity? What specific concepts must they learn and what ideas must they acquire to support that understanding? What class work, materials, curriculum, set of courses, and experiences would provide an adequate background so that they come to an understanding of this concept?

In 1985 the American Association for the Advancement of Science (AAAS) began Project 2061, a long-term initiative to reform K–12 education in natural and social sciences, mathematics, and technology. *Science for All Americans*, published in 1989, was conceived as a statement of learning goals for science, mathematics, and technology education, defining what all students should know and be able to do by the time they conclude secondary education. *Science for All Americans* includes learning goals related to biodiversity (see Box 1).

<td>Diversity of Life</td>
<td>Millions of different types of individual organisms inhabit the earth at any one time—some very similar to each other, some very different. Biologists classify organisms into a hierarchy of groups and subgroups on the basis of similarities and differences in their structure and behavior. One of the most general distinctions among organisms is between plants, which get their energy directly from sunlight, and animals, which consume the energy-rich foods initially synthesized by plants. But not all organisms are clearly one or the other. For example, there are single-celled organisms without organized nuclei (bacteria) that are classified as a distinct group. Animals and plants have a great variety of body plans, with different overall structures and arrangements of internal parts to perform the basic operations of making or finding food, deriving energy and materials from it, synthesizing new materials, and reproducing. When scientists classify organisms, they consider details of anatomy to be more relevant than behavior or general appearance. For example, because of such features as milk-producing glands and brain structure, whales and bats are classified as being more nearly alike than are whales and fish or bats and birds. At different degrees of relatedness, dogs are classified with fish as having backbones, with cows as having hair, and with cats as being meat eaters. For sexually reproducing organisms, a species comprises all organisms that can mate with one another to produce fertile offspring. The definition of species is not precise, however; at the boundaries it may be difficult to decide on the exact classification of a particular organism. Indeed, classification systems are not part of nature. Rather, they are frameworks created by biologists for describing the vast diversity of organisms, suggesting relationships among living things, and framing research questions. The variety of the earth's life forms is apparent not only from the study of anatomical and behavioral similarities and differences among organisms but also from the study of similarities and differences among their molecules. The most complex molecules built up in living organisms are chains of smaller molecules. The various kinds of small</td>
</tr>
</tbody>
</table>
molecules are much the same in all life forms, but the specific sequences of components that make up the very complex molecules are characteristic of a given species. For example, DNA molecules are long chains linking just four kinds of smaller molecules, whose precise sequence encodes genetic information. The closeness or remoteness of the relationship between organisms can be inferred from the extent to which their DNA sequences are similar. The relatedness of organisms inferred from similarity in their molecular structure closely matches the classification based on anatomical similarities.

The preservation of a diversity of species is important to human beings. We depend on two food webs to obtain the energy and materials necessary for life. One starts with microscopic ocean plants and seaweed and includes animals that feed on them and animals that feed on those animals. The other one begins with land plants and includes animals that feed on them, and so forth. The elaborate interdependencies among species stabilize these food webs. Minor disruptions in a particular location tend to lead to changes that eventually restore the system. But large disturbances of living populations or their environments may result in irreversible changes in the food webs. Maintaining diversity increases the likelihood that some varieties will have characteristics suitable to survival under changed conditions. As noted in Science for All Americans, Project 2061, from the American Association for the Advancement of Science:

Our planet’s essential goods and services depend on the variety and variability of genes, species, populations and ecosystems. Biological resources feed and clothe us and provide housing, medicines and spiritual nourishment. The natural ecosystems of forests, savannahs, pastures and rangelands, deserts, tundras, rivers, lakes and seas contain most of the Earth’s biodiversity. Farmers’ fields and gardens are also of great importance as repositories, while gene banks, botanical gardens, zoos and other germplasm repositories make a small but significant contribution. The current decline in biodiversity is largely the result of human activity and represents a serious threat to human development. (1989, pp. 60–61).

• Some animals and plants are alike in the way they look and in the things they do, and others are very different from one another.
• Plants and animals have features that help them live in different environments.
• Stories sometimes give plants and animals attributes they really do not have.

Recommended learning activities include providing students the opportunity to observe a variety of plants and animals in the classroom; on the school grounds; in the community; at home in parks, streams, and gardens; and at the zoo. The observations would prompt students to pursue questions about how the organisms live, where they are found, or how they interact with other organisms.

B. Grades 3–5

For children in later primary education, Benchmarks recommends that students learn the following:

• A great variety of kinds of living things can be sorted into groups in many ways using various features to decide which things belong to which group.
• Features used for grouping depend on the purpose of the grouping.

Recommended learning activities include providing students the opportunity to learn about an increasing variety of living organisms and offering them a chance to invent schemes for classification. Students would be encouraged to develop different classification schemes (without being introduced to the Linnean classification system) and shown how their usefulness varies depending on the purpose of the classification. The purpose of the work would be to help students develop a deeper understanding about the relatedness of organisms.

C. Grades 6–8

For children in upper primary and lower secondary education Benchmarks argues that science should provide students with opportunities to enrich their growing knowledge of the diversity of life on the planet and to begin to connect that knowledge to what they are learning in geography. That is, whenever students study a particular region in the world, they should learn about the plants and
animals found there and how they are like or unlike those found elsewhere.

Food patterns of development and external and internal structures would all be used to illustrate interrelationships, interdependence, similarities, and differences. Students would be introduced to the features that biologists use in classification systems and would be taught why these classifications are made.

Benchmarks suggests that students in this group should know the following:

• One of the most general distinctions among organisms is between plants, which use sunlight to make their own food, and animals, which consume energy-rich foods. Some kinds of organisms, many of them microscopic, cannot be neatly classified as either plants or animals.

• Animals and plants have a great variety of body plans and internal structures that contribute to their being able to make or find food and reproduce.

• Similarities among organisms are found in internal anatomical features, which can be used to infer the degree of relatedness among organisms. In classifying organisms, biologists consider details of internal and external structures to be more important than behavior or general appearance.

• For sexually reproducing organisms, a species comprises all organisms that can mate with one another to produce fertile offspring.

• All organisms, including the human species, are part of and depend on two main interconnected global food webs. One includes microscopic ocean plants, the animals that feed on them, and finally the animals that feed on those animals. The other web includes land plants, the animals that feed on them, and so forth. The cycles continue indefinitely because organisms decompose after death to return food material to the environment.

D. Grades 9–12

For students at the secondary level, curricular objectives lead to understanding diversity within and among species by looking at ‘same and different’ features at a molecular level. Students would learn the following:

• The variation of organisms within a species increases the likelihood that at least some members of the species will survive under changed environmental conditions, and a great diversity of species increases the chance that at least some living things will survive in the face of large changes in the environment.

• The degrees of kinship between organisms or species can be estimated from the similarity of their DNA sequences, which often closely matches their classification based on anatomical similarities.

Understanding built up over this period of study would lead students to comprehend the diversity of ecosystems, diversity of species, and the genetic diversity within species.

While Benchmarks sets out a recommended sequence of learning goals to help students come to an understanding of biodiversity as a complex idea, it is not clear that most students have access to the education, ideas, concepts, and learning experiences needed to achieve such understandings. Therefore it would be necessary to explore what students are taught or expected to learn over time during their schooling.

E. Biodiversity and School Science

Formal education in science is an important contributor to students’ fundamental understandings about science. While self-directed study—books, articles, the Internet, museum visits, and field experiences—augment science learning for many students, the quality of the curriculum, textbooks, and other instructional materials, the preparation of teachers, the school-mediated experiences provided to students both inside and outside of the classroom all interact to shape what students take away from school science. Understandings of biodiversity would be based on accumulated experiences and knowledge. These would include the early school focus on ‘natural history’ and ‘nature study’ and development of an ‘intuitive’ understanding of biological diversity and the relationships among living organisms (National Research Council, 1990). Students’ out-of-school experiences, where such are available, would reinforce school learning. The curriculum focus shifts in lower and upper secondary levels (grades 6–12) to more formal, taxonomic instruction.

This pattern of topic coverage for life sciences concepts is present in the curriculum of other countries around the world and was prevalent among the majority of the 50 educational systems of countries that participated in the Third Mathematics and Science Study (or TIMSS). Data were collected in 1993 and results presented in 1996.

In the United States, according to statistics provided by the U. S. Department of Education, biology is the most frequently taken high school science course, with over 93% of 1994 graduates of public high schools
reporting having completed such a class. Over 97% of graduates from nonpublic high schools reported completing biology. Analysis of content core is not available to determine the extent to which the ideas critical to a student’s understanding of biodiversity are actually taught. It is also not clear if earlier foundational ideas are provided to students as a part of instruction at primary and lower secondary levels.

In the United States there has been considerable discussion about the adequacy, pacing and structure of curriculum and, especially, of textbooks in middle and high school biology. Researchers have criticized their ‘encyclopedic’ nature, with too many ideas covered too superficially, and too much focus on vocabulary at the expense of big ideas. A recent study that evaluated the science textbooks used in middle grades against three concepts from Benchmarks and Standards, one each from the earth, physical, and life sciences, led AAAS Project 2061 to conclude that all nine titles examined were inadequate to help students achieve understanding of the ideas that they were attempting to explain.

Efforts to actually measure what students know about science are undertaken through the regularly administered National Assessment of Educational Progress and recently have been internationally benchmarked through TIMSS. At lower and upper secondary levels, the results suggest that U. S. students gain little real understanding of the big ideas of science, including life sciences, in spite of the fact that they are most likely to have had formal classes in this area than in other areas of science. It has largely been in the study of biology that the basic concepts of biodiversity have been advanced; diversity within species, across species and ecosystems; relatedness of species; interdependence among living things; threats to this diversity due to population pressures; loss of habitat; changes in species over time; natural extinctions; and human induced extinctions. While biodiversity and biodiversity education are more recent concepts, nature study, conservation, and environmental education have older roots, in a more general emphasis on environmental improvement and appreciation. The following section will explore some of the history of environmental education and consider how it might relate to biodiversity education.

### III. ENVIRONMENTAL EDUCATION

In 1977 the world’s first intergovernmental conference on environmental education was organized by the United Nations Environment Programme and held in Tbilisi, Georgia (Soviet Union). The Tbilisi Declaration, adopted at the conference, stressed the importance of environmental education in the preservation and improvement of the world’s environment. Agenda 21, Chapter 36, outlines issues related to formal education, public awareness and training to promote sustainable development and emphasizes environmental and development education as an essential aspect of all education. There were also calls for linking to environmental education in recommendations from the World Conference on Education for All (held in Jomtien, Thailand in 1990) that urged a move toward universal access to basic education for girls and boys.

The recommendations include calls for better informal education, promotion of environmentally sound leisure and tourism activities, programs to involve young people and children, as well as respect for and support of efforts to promote dissemination of traditional and socially learned knowledge through mechanisms based in local cultures.

Environmental education was called “nature study” when it got its start in the 1920s with Junior Audubon Clubs teaching children to appreciate nature. According to Karen Schmidt in a December 13, 1996, article in Science, the movement was transformed into conservation education in the 1930s when the Dust Bowl environmental tragedy led to incorporation of ideas into some schools about the management of natural resources.

With the initiation of Earth Day in 1970 and passage of the National Environmental Education Act of 1970, teachers received supplemental training in environmental education. Many states enacted their own environmental education laws, and schools began incorporating these topics into science classes. On the 20th anniversary of Earth Day, President Bush signed the National Environmental Education Act of 1990, which created an Office of Environmental Education at the Environmental Protection Agency and supported curriculum development and teacher training in the states.

In the United States concern has been expressed about the place of environmental education, as currently configured into the curriculum, and especially about the quality of programs sometimes offered in lower secondary schools. This has included concerns about an advocacy orientation in instruction, about the need for and balance in materials used and instruction provided. The North American Association for Environmental Education (NAAEE), a professional group that includes college faculty and K–12 educators among its members, developed “Guidelines for Excellence” to help guide teachers and others in the selection of quality, balanced materials.
Teaming with Life makes a strong recommendation that environmental education have a stronger base in science, using scientifically grounded curricula. Innovative programs such as GLOBE (see Box 2) that depend on student-scientist partnerships and collection of real data may point the way to science education based around environmental and biodiversity concerns.

In 1996 a national conference held in Washington, D.C., spotlighted projects that depended on student-scientist partnerships, including a number that focused on biodiversity as learning themes. Included among these were “Classroom Feederwatch,” a program of authentic research for grades 5–8 developed by Cornell Laboratory of Ornithology and TERC, with funding from the National Science Foundation. In this program, students (and their teachers) learn to identify birds, to ask scientific questions and to design experiments to answer them. Students analyze and display data to answer their questions and collect and share data in a research database used by professional ornithologists in their studies of bird populations. Students thus become part of a larger team of those contributing to biodiversity studies. (For more information see http://birdsource.cornell.edu/cfw/watiscf.htm.)

IV. LEARNING IN THE INFORMAL EDUCATION SECTOR

A. Overview

A wide range of informal education experiences are available for adults and children to extend their knowledge about biodiversity. These include organizations that incorporate biodiversity education and exhibition within their missions, such as the following:

- Zoos
- Botanical gardens
- Aquariums
- Museums
- National parks

Depending on their size, these “places of science” might also incorporate research, collections, conservation, or other functions important to biodiversity. Signage and docent-led and audio tours provide additional information to visitors. Classes, lectures, and workshops (including those for teachers) are also often provided to

Box 2

Global Learning and Observation to Benefit the Environment (GLOBE)

GLOBE, a hands-on, school-based international environmental science program, was introduced by U.S. Vice President Al Gore in April 1994 and began operation on Earth Day in April 1995. In 1999 there were more than 6000 participating schools in more than 70 countries. GLOBE brings together students, teachers, and scientists from around the world to enhance environmental awareness of individuals worldwide, increase scientific understanding of the earth, and support improved student achievement in science and mathematics.

Students make environmental observations, or take environmental measurements near their school site, report their observations via the Internet, receive and use GLOBE images created from the combined data, and study the environment by relating their observations to larger environmental topics. GLOBE educational materials were developed by environmental educators and curriculum development specialists working with scientists. Materials are used in schools under the guidance of teachers who have received training using GLOBE materials. Teachers include GLOBE activities as appropriate within their local curricula. GLOBE materials are translated into the six United Nations’ languages (Arabic, Chinese, English, French, Russian, and Spanish) and are also available in Czech, Estonian, German, Greek, Hebrew, and Japanese. GLOBE international partners sign bilateral agreements with the United States and manage participation of schools in their countries. In the United States, GLOBE is administered by an interagency team that includes the National Oceanic and Atmospheric Administration, the National Aeronautics and Space Administration, the National Science Foundation, the Environmental Protection Agency, the Departments of State and Education, and others.

Observations range from basic weather parameters (temperature, atmospheric pressure, and precipitation) to measurements such as water chemistry, biodiversity, and biomass assessment. The focus to date has been more heavily directed toward physical systems measurements. Potential is great to increase the biodiversity and life systems aspects of the project.
extend the learning experience. Increasingly, materials and web sites incorporate aspects of a visit, bringing resources to audiences at a distance to make some part of the visitor experience remotely available.

Informal education also includes more intensive immersion experiences such as where it is incorporated into visits to natural preserves such as parks (including those within national park systems) and forests, or that provided through ecotourism.

Interpretive programs using volunteers, staff, and written and video materials provide enhanced learning experiences by bringing the science, the issues, and the concerns into sharp focus as a part of the overall environmental experience. Programs such as Earthwatch have biodiversity-focused visits that involve the participant in the research as data collector. Other informal learning opportunities are available through television and IMAX programs, web sites, and books.

Youth-serving groups provide a broad range of activities and experiences that can support education around concepts of biodiversity (see Box 3). Many may involve long-term projects of environmental monitoring, animal and plant breeding, habitat restoration, and other activities undertaken individually or in groups.

Box 3
Selected Youth Serving Groups Providing Informal Science/Environmental Education

American Camping Association (ACA)
Founded in 1910 ACA provides an accrediting mechanism for camps. Of the more than 2200 accredited camps listed, 284 provided nature/environmental study as part of the camp experience.

Boy Scouts of America (BSA)
Enrollment: 5.6 million
Program: Incorporated in 1910 BSA provides programs for boys that include outdoor skills, nature study, and conservation activities through an elaborated badge structure and group activities. BSA is a charter member of the World Scout Conference.

Camp Fire Boys and Girls
Enrollment: 667,000 young people (birth–age 21)
Program: Camping and environmental education programs offering children an appreciation and commitment to the natural environment.

Girls Incorporated
Enrollment: 350,000 girls (ages 6–18) at more than 1000 sites nationwide
Program: Activities include experiences in mathematics and science education through Operation SMART

Girl Scouts of the U.S.A. (GSUSA)
Enrollment: 3.5 million
Program: Activities include out-of-doors, nature study. Badge structure that includes environmental issues. GSUSA is member of the World Association of Girl Guides and Girl Scouts.

World Association of Girl Guides and Girl Scouts undertakes world projects including building world citizenship. Environment is one of the themes of this program.

National 4-H Clubs
Enrollment: 6.0 million in more than 76,500 clubs
Program: Part of the U.S. Department of Agriculture’s Cooperative Extension Service established in 1914. Project areas include agricultural and natural sciences, and technology, Cornell Nest Box network.
B. Zoos and Other “Places of Science”

Animal parks were established by and for rulers. Maier and Page, in their volume Zoo: The Modern Ark (1990), describe how animals were kept by royalty for entertainment and as a show of wealth. The third dynasty ruler of the Sumerian city of Ur had a park that dated around 2300 B.C. A millennium later as civilization spread in the Near East and Asia, rulers and pharaohs exchanged “exotic” animals for their zoos. Emperor Wu Wang of the Chou dynasty laid out a zoological garden called the Park of Intelligence. Animal collections were found around the globe in early civilizations such as in Egypt some 3500 years ago.

Alexander the Great, perhaps influenced by Aristotle’s private menagerie, installed what was perhaps the first public zoo in Alexandria, Egypt. With the coming of the “Dark Ages” of Europe, monasteries became the keepers of menageries and game parks. When Cortes arrived in the Aztec capital of Tenochtitlan, he found a large zoo behind Emperor Montezuma’s palace. Zoos in India were established by Akbar toward the end of the 16th century. He, like the Aztecs, employed people specially trained to care for and medically tend to animals.

The zoo at Vienna was reinvigorated by Maria Theresa and her husband as the Imperial Menagerie at Schönbrun for the convenience and entertainment of the nobility. The zoo remains today as likely the oldest in continuous operation, dating from the 1750s. Democratization of Europe and establishment of urban centers that accompanied industrialization led to the “modern zoo” as a repository of exotic specimens of life that were to be studied as a way of understanding “flora and fauna” of the world. Public monies (rather than private patrons or royal largesse) were available to begin systematic scholarly study. Maier and Page date the modern zoo to 1826 when the Zoological Society of London founded the zoological gardens at Regent’s Park for the purpose of understanding the natural history of the animals inhabiting the reaches of the British Empire.

Since zoos as public institutions had to raise funds and attract money (independent of their research and conservation goals), they had to become popular attractions. Zoo organizers also had to learn to manage space and figure out and meet animals’ requirements, such as for social interaction. Zoo’s role in conservation became educational as they raised visitor awareness about endangered species and loss of habitat. Where larger zoos also developed significant breeding herds, they established breeding farms. In San Diego, for example, this “wild animal park” has become an additional attraction.

The National Zoological Park (National Zoo), associated with the Smithsonian Institution, established a “biopark,” Amazonia, to emphasize the relationships among soil, plant, invertebrate, and other animal forms and the need to preserve the habitats of the world. Zoos, aquariums, and game parks are being seen as tools to affect public attitudes regarding the variety of life on earth. As these “places of science” intentionally blend education and entertainment they are increasingly adding materials from museum collections and incorporating interactive exhibits from science—technology centers to reinforce conservation messages, concern about loss of species numbers, and diversity and loss of habitat.

1. Botanical Gardens

In 1989 the World Resources Institute estimated that 150 million persons visited some 1500 botanical gardens around the world. In addition to visits and guided tours, gardens offered continuing education for adults, workshops and hands-on experiences for children and families, and professional education courses and seminars for K–12 teachers. The New York Botanical Garden and Missouri Botanical Garden are examples of two of 21 member gardens of the American Association of Botanical Gardens and Arboreta offering graduate studies programs, usually in collaboration with universities in their area.

2. Museums

Through collections, education programs, exhibitions, and graduate-level research, museums have been very active in promoting biodiversity in both the formal and informal sectors. The American Museum of Natural History in New York (AMNH) provides an interesting example of an institution with current involvement in all these areas:

- **Exhibition.** The 11,000-square-foot Hall of Biodiversity is the newest permanent exhibit of AMNH and uses collections, interactive technologies, and an immersive environmental replica of a portion of the rain forest of the Central African Republic—complete with sound, smell, movement, and running water—to provide a unique visitor experience.
- **Graduate and continuing education.** The Center for Biodiversity and Conservation collaborates within and outside the museum in the development of courses and programs. AMNH is home to the oldest and largest doctoral and postdoctoral training...
program of any scientific museum in the world, collaborating with Yale, Columbia, Cornell, and City University of New York.

- **Education.** The National Center for Science Literacy, Education and Technology supported by the National Aeronautics and Space Administration (NASA) has developed a number of projects related to the theme of biodiversity, including **Biodiversity Counts: A Student Inventory Project**, a program for middle school students across the United States to inventory plant and animal life in their communities and to share their findings through publications and on-line field journals.

### C. Biodiversity "Experiences" and Resources

**Overview**

For most adults, biodiversity education will take place in the informal sector as they read books; visit zoos, museums, and national parks; listen to lectures; and watch programs on the increasing number of science- and nature-based cable channels, public television, or the increased coverage of science on the news or news magazines. Others will visit the World Wide Web, where an increasing number of excellent sites developed by universities, museums, federal agencies, and non-profit organizations provide high-quality information. Several examples of resources for biodiversity education available to the adult public follow.

1. **Earthwatch**

   Earthwatch Institute is an international nonprofit organization founded in 1971 that supports scientific field research worldwide. Volunteers participate in actual field research, assisting scientists in gathering data. Since its beginnings it has "mobilized 150 projects around the globe, resulting in the discovery of 2000 species, the establishment of 12 national parks, and the founding of eight museums." The Earthwatch web site lists active projects that volunteers can join in seven topical areas including Endangered Ecosystems and Biodiversity. The site also includes virtual field trips. Visit [http://www.earthwatch.org](http://www.earthwatch.org).

2. **National Biological Information Infrastructure (NBII)**

   The NBII attempts to organize the disparate sources of information available through agencies, departments, museums, and other organizations, providing a source of links to sites. A "Biodiversity, Systematics and Collections" section connects to other web sites, many of which have education or "for kids" sections. Many federal agencies such as the U.S. Geological Survey, the Environmental Protection Agency, NASA, and others have relevant sites. Visit [http://www.nbii.gov/biodiversity](http://www.nbii.gov/biodiversity).

3. **Nonprofit Environmental and Biodiversity Groups**

   A number of organizations produce materials to support education about environmental and biodiversity issues. These include groups such as the World Wildlife Fund, the Sierra Club, and the Audubon Society. These groups develop a wide variety of public information and educational materials.

   While most mainstream advocacy groups are conscious of the need to "get the science right" and to present balanced viewpoints concerns are sometimes expressed about school use of materials that emanate from an "advocacy position." Guidelines have been developed by NAAEE to assist educators in assessing the scientific accuracy of such materials.

### V. PUBLIC AWARENESS

How much does the public understand about environmental issues in general and biodiversity in particular, and what are the attitudes toward these issues? Surveys from a number of sources indicate that there is strong public interest in and support for issues related to the environment. The National Science Board's *Science and Engineering Indicators* (1998) suggested strong interest and "informedness" of the public around environment and health topics, especially when compared with other science and technology areas, and interest and support were stronger among women than men. The National Environmental Report card, an attitudinal and knowledge survey of American adults conducted by the National Environmental Education and Training Foundation and Roper Starch Worldwide, concluded that there was "an alarming lack of knowledge about some of our most critical environmental problems." With regard to biodiversity, however, 73% of adults surveyed correctly responded about the direct relationship between species loss and habitat destruction.

In 1995 the Consultative Group on Biological Diversity initiated the Biodiversity Project, a public education effort by a nonprofit grant makers' forum to "assess public opinion on biodiversity, to develop collaborative strategies to increase public awareness and engagement, and lay the groundwork to implement those strategies."
In June 1998 a “summit” on biodiversity and environmental education was convened at the American Museum of Natural History as a Biodiversity Educators Summit. The summit was supported by evidence from focus groups and surveys and co-convened by The Project, AMNH, and World Wildlife Fund. The 1996 Biodiversity Poll, conducted by the public opinion research firms Belden & Russonello and R/S/M and reported at the Summit, revealed the following about the environment and biodiversity:

- People care about the environment, but it isn’t in the top tier of public concerns.
- Of environmental concerns, the public considers the most serious problems to be toxic waste, destruction of the rain forest, loss of places in nature, and air and water quality.
- Extinction is a concern, but it is not high on the list.
- People understand that nature is connected and interdependent, but most people do not recognize or use the word biodiversity. Only 2 in 10 said they had heard about the “loss of biological diversity.”
- The public understands that species are declining and that human activity is largely responsible. But the public does not understand much about specific reasons or about the seriousness of the rate of loss.
- Public support for biodiversity conservation (once biodiversity is explained) is wide—87%. But this support is shallow.
- Countervailing pressures (values) can peel support away from biodiversity protection. These include concerns about jobs, individual property rights, comfort and convenience, and preservation of “unattractive” species. However, 91% of Americans agree that the world would suffer if such “unattractive species” (e.g., mosquitoes) are eliminated.

The gap may relate to the following:

- A general lack of attention to biodiversity and its consequences by the media
- The way that the public message about biodiversity is conveyed
- The biological understandings that members of the public bring to the discussion

Interestingly, the spottiness of adult knowledge and concepts (some individual ideas understood, but not the overall concepts nor the consequences that flow from them) tracks with observations made about the K–12 student understanding of life sciences ideas. For most members of the public, high school is the last time for a formal course in the life sciences. After that, they generally rely on the informal sector for additional information and updates to their knowledge.

VI. COLLEGES AND UNIVERSITIES

According to Science and Engineering Indicators, persons taking college-level science courses are more likely to be informed about, supportive of, and interested in science and technology topics. College level courses in biology influence knowledge and attitudes of the public. Beyond Biology 101, produced by the Howard Hughes Medical Institute, describes efforts to transform college-level courses in biology for both majors and nonmajors, moving away from vocabulary-driven courses to ones that are more integrative and that include meaningful laboratory and field experiences. A number of programs are described at http://www.hhmi.org/BeyondBio101.

These include an innovative program in human biology developed and in place since the 1960s at Stanford University. The program, taught by faculty from biology, education, anthropology, psychology, and other disciplines, focuses on the relationship between human biology and human behavior including human interactions with environment. It is a major course of interdis-
The program for majors involves students in a range of activities designed to get them to think like scientists. Biodiversity and human impacts on the environment are explicit foci of instruction, and in the late 1980s and 1990s the college program was “translated” into a middle grades life sciences project (HumBio). Biodiversity concepts and activities are explicitly included among the curriculum materials in the ecology theme. While most four-year institutions offer majors in biology or related specialties (including ecology), biodiversity was found as an area of major concentration at only a few U.S. colleges and universities. A search of the site, Academic Programs in Conservation Biology (http://www.conbio.rice.edu/programs), yielded programs at Columbia University, Illinois State University, San Diego State University, State University of New York at Albany, University of California at Riverside, University of Massachusetts at Amherst, University of Southwestern Louisiana, University of Wisconsin at Madison, and Yale University. Searches for “sustainable development” added to this list programs at Cornell University, Harvard University, University of Georgia, University of Maryland, University of Miami, and University of Minnesota. Distance learning classes were also available in these fields and listed at http://eelink.net.

Other countries that have evidence of strong interest in collegiate and university studies in biodiversity include Canada and Australia. The United Nations University, Institute for Natural Resources in Africa (UNU/INRA) has a number of relevant programs in the following categories:

- Soil and water management: Soil fertility restoration and maintenance.
- Conservation of biodiversity: Genetic improvement and increased utilization of Africa's indigenous food crops and useful plants
- Conservation and management of mineral resources.

Education and training are key areas of interest to UNU/INRA. In cooperation with other agencies of the UN, the program develops curriculum and contributes to training in areas such as ecological economics, natural resource economics and environmental accounting, germplasm and biodiversity conservation, wildlife management, and taxonomy. Gender and Natural Resources is a major cross-cutting theme in the work of the institute.

VII. SYSTEMATICS RESEARCH AND TRAINING

While the demand for expertise in conservation, biodiversity, and systematics has been increasing, concern is being expressed about the human resources, especially in developing countries, available to manage and inform natural resources utilization around the globe. A 1995 workshop on Priorities in Systematics Research and Training organized by the United Kingdom Systematics Forum and held at the Linnean Society of London raised issues about the adequacy of support for systematic biology, the declining interest in systematics among students, and the decline in the teaching of systematics in many universities. A search for university departments worldwide that provide training in systematics and taxonomy revealed 24 institutions, 10 in the United States. This may be deceptive, however, in that a number of institutions provide graduate training in partnership with research-oriented museums and botanical gardens. New emphases such as work in molecular systematics may exist in cellular, molecular, microbiology or biochemistry programs. BIO NET-INTERNATIONAL is a global network of people and institutions that develop biosystematics capacity in developing countries. Training at all levels (in service, short courses, distance courses, and joint graduate programs) is a major focus of the network’s activities.

VIII. CONCLUSION

A combination of school-based learning and out of school experiences combine to provide young people with knowledge of and attitudes about biodiversity that they then take into adulthood. For those who pursue higher education, college-level courses are available in some institutions that integrate biodiversity education into larger biological, environmental, or human impacts courses. Other adults must depend on the informal education sector, with experiences provided by a variety of different institutions and media. Biodiversity education may also, in some cultures, rely on community transmission of locally held knowledge of plants and animals of a region. Whatever the process for developing understanding, education and public awareness have been seen as crucial precursors to building support for biodiversity.

I. INTRODUCTION

Endangerment is the condition in which a species or subspecies of animal or plant is at risk of extinction. The nature of the impending extinction may be local, national, or global. There is no vocabulary to differentiate between these conditions; as a consequence, there is often confusion over appropriate priority levels. A trend to use extirpation to indicate nonglobal extinction brings its own problems, since the active verb extirpate is synonymous with eradicate; there is also the problem that disappearing subspecies of species may be both extinct and extirpated (extinct as taxonomically distinct forms, extirpated as representatives of a higher taxonomic unit). This article concentrates primarily on bird species at risk of global extinction, but nationally and locally endangered forms, including subspecies, are also considered; so extirpated is here used to mean locally extinct. The terms endangered, threatened, and at risk
are commonly used interchangeably; endangered is prevalent in U.S. usage, but IUCN/The World Conservation Union status categories use threatened as a generic term and Endangered (with a capital E) for a particular status. In this article, endangered is preferred, except in contexts involving the IUCN threat categories.

II. THE IDENTIFICATION OF ENDANGERED BIRDS

A. Taxonomy and the Identification of Target Units

In general, decision makers look to science in two ways for help in establishing priorities in species conservation: the first is the degree of a taxon's risk of extinction, and the second is the degree of its evolutionary differentiation. Many people are surprised that these aspects, particularly the second, remain hard to assess. Ever since the passing of the United States Endangered Species Act, the term “endangered species” has become widely used in popular and indeed jocular English parlance; so it seems extraordinary that debate still rages over what a species is. Nonetheless, its definition is a pervasive problem, and the profile of this issue will increase as more morphologically distinct, local forms, currently considered subspecies, come under pressure from human development activities.

When considering closely related taxa in which there is no geographical contact, and therefore no test for reproductive isolation (the key criterion under the prevalent Biological Species Concept or BSC), taxonomists are compelled to rely on the degree of their morphological similarity to judge, subjectively, whether they are conspecific or not. Among birds there are thousands of such cases, in part because flight has allowed them to colonize so many offshore and oceanic islands, where they have evolved features that distinguish them at some level from continental or other island stock.

Some influential museum-based ornithologists have recently advocated a narrow phylogenetic species concept (PSC), which bestows species-level identity on any population whose members fully share distinct characters, irrespective of hybrid zones. Many of these populations currently have taxonomic standing as subspecies, and proponents of the PSC expect its adoption to cause a doubling of the number of avian species, to about 20,000 from the roughly 9500 in current usage. However, BSC supporters contend that, rather than clarifying the status of disjunct populations, the PSC shifts the difficulty to a yet more complex and subjective level, where very minor differences (sometimes biochemical only, and certainly not used to recognize even subspecies) may or may not be regarded as sufficiently distinct and consistent to admit species-level status, so that no final number of avian species can be even approximated.

This debate is important, not least because biological diversity is directly at stake. Some years ago the BirdLife Red Data Book program eliminated subspecies from its concern, on the basis that there were simply too many to document and that species had to take priority. This decision, made with the knowledge that many threatened subspecies will benefit from site management for threatened species with which they are sympatric, still tends to expose some subspecies, especially those with small ranges and therefore with relatively constrained populations, to the vagaries of deteriorating global conditions. Unless a country is as wealthy as the United States, whose legislation embraces subspecies and independent populations, or has little or no other biological heritage in which to invest (for birds, Barbados is one such), the chances of intervention on behalf of these forms are relatively low.

Nevertheless, subspecies are far less stable as taxonomic entities than are species, and are easily erected and just as easily subsumed (prior to 1950 at least two museum ornithologists, Oberholser and Koelz, each established over 100 subspecies in the course of a single paper!). Because of this, they are generally unwelcome in law, which requires widespread long-term agreement on taxonomy to be able to function. Consequently, species rather than subspecies are the units of concern in most national and international legislation. Partly perhaps as a consequence of this, many ornithologists seem willing to countenance the steady, consistent “unlumping” of many forms, on the basis of multiple character differences extending beyond morphology to voice, behavior, and even habitat. For conservation purposes this process needs to be expedited to ensure that specific identity is not bestowed too late for intervention. However, the elevation of many weakly distinct forms to species level may actually make the identification of conservation targets harder, for if resources are insufficient to support all the resulting endangered species, many deserving cases (in terms of their evolutionary distinctiveness) might be lost amid the competing claims of virtual look-alikes.

B. Scale and the Identification of Target Units

Birds can be endangered at the global, broad regional (e.g., subcontinental), national, narrow regional (e.g.,
Global endangerment is the most important priority level, since total extinction is a far worse risk than any other form. In the past 35 years or so, global endangerment of birds has been registered principally through the Red Data Book program of the International Council for Bird Preservation (now BirdLife International). This program, accepted by IUCN/The World Conservation Union as the official source of globally threatened bird listings, has developed into a long-term, continent-oriented project to create detailed profiles of every endangered species (Collar and Stuart, 1985; Collar et al., 1992; Collar et al., 1999), based on the rationale that all information relevant to a species’s conservation should be included. This in turn has led to the need for abbreviated global listings (Collar et al., 1994).

The species that have found their way into these full and abbreviated Red Data Books are normally found on national “red lists,” but not always at the expected priority level, owing to the various algorithms that non-global assessment tends to involve. Thus an apparently priority level, owing to the various algorithms that non-abbreviated Red Data Books are normally found on these parameters as well as on decline rate by which to measure eligibility for and degree of threatened status. In IUCN terminology, the word threatened means what has hitherto been called endangered, whereas “Endangered” denotes a specific conservation status.

In crude form, the criteria stipulate that, to qualify as threatened, a species must possess a total population (A) declining at a rate (projected or past) of 20% over 10 years or three generations, or (B) within a range of less than 20,000 km² and declining, or (C) of less than 10,000 mature individuals and declining, or (D1) of less than 1000 mature individuals, or (D2) within a range of less than 100 km². Species meeting any one of these criteria qualify as threatened with the category Vulnerable; nested thresholds qualify species for the categories Endangered and Critically Endangered. Sub-species can be subjected to the same criteria, but this may result in the curious circumstance where all races of a species qualify as at risk (e.g., all five races of an island species with declining populations of under 10,000) but the species itself does not (total population still above 40,000).

The general experience with birds, almost certainly as with all animals and plants, is that populations tend to be significantly underestimated: for example, one observer on the New Caledonian island of Uvea judged there to be 70–90 Uvea (Horned) Parakeets (Eunymphicus cornutus) in 1993, but more intensive fieldwork later that year yielded a formal estimate of 617 ± 379. Similarly, a CAMP (Conservation Assessment and Management Plan) run by the Captive Breeding Specialist Group of IUCN in 1992 suggested a total
population of some 5000 Tanimbar Corellas (Cacatua goffini), whereas analysis of quantified data from fieldwork that same year produced an estimate of 300,000–400,000 birds. Consequently, lists of threatened species cannot be expected to remain stable: while some will be added over time as their situation deteriorates or their taxonomy is revised, others will be removed as their true status is revealed.

In 1988, 1030 bird species were identified as at risk of extinction. In 1994, this figure, based on the new IUCN criteria, rose to 1111. It was not, however, the case that 81 species were added to the 1988 complement. In fact only 816 species were common to both lists. The 214 disappearances from and 295 additions to the 1994 list largely resulted from new “pioneering” knowledge (involving new areas or new identification insights) rather than from “monitoring” updates that disclosed a clear trend. Exploration is thus still the strongest biological data source, and “rare” species (for which see Kunin and Gaston, 1998) sometimes prove to be relatively common in some part of their range, or in some previously uninvestigated habitat. Consequently, attempts to predict future extinction rates using changes in red lists have been premature: the changes in question are not real-world events (Crosby et al., 1996).

A degree of red list stability derives from some species being destined to remain endangered in perpetuity. This is because of their irremediably small ranges or populations (a circumstance that has made the criteria unpopular in some quarters, since no active threat need exist to trigger the listing). These are species—avian examples including the Lava Gull (Larus fuliginosus), with 300–400 pairs maximum, and the Tinian Monarch (Monarcha takatsukasae), on an island of less than 100 km² despite its estimated 40,000 individuals—for which the price of survival is eternal vigilance.

Appropriate criteria for use at the national level are still under development by IUCN; meanwhile, a good model is that of Avery et al. (in Coulson and Crockett, 1995).

III. TRENDS AND FACTORS IN THE ENDANGERMENT OF BIRDS

A. Globally Threatened Birds in 1994: Numbers, Criteria, and Extinction Rate Predictions

The 1111 bird species judged to be at risk of extinction in 1994 represented 11% of the world’s avifauna. Moreover, a further 66 (1%) species were then listed as Data Deficient and 875 (9%) as Near-Threatened, so that altogether over 20% of all bird species were identified as being of some global conservation concern. The majority of threatened species were classified as Vulnerable (704, 63%), with 233 (21%) Endangered and 168 (13%) Critically Endangered.

The commonest criterion triggered by threatened birds was C, which combines small population (<10,000) with significant decline. As many as 764 species (approaching 70%) of all threatened birds were judged (or, under the precautionary principle, thought likely) to fulfill this criterion; thus 8% of all bird species are known or suspected to have dangerously low populations. The other four criteria proved to be rather evenly distributed: A (rapid decline) and B (small range with significant decline) were triggered by around 400 species each, with somewhat smaller numbers triggering D1 (very small population) and D2 (very small range).

The new IUCN criteria attach hypothetical probabilities of extinction to the different categories of threat, on which basis 400 species may be expected to become extinct, without remedial action, in the coming century, however, it will take 1750 years for 90% of the 1111 listed threatened species to disappear. Comparison with the 1988 listing allowed three different listing recruitment rates to be tested on two models, indicating that with current trends between 400 and 1200 species of bird may die out within the next 100 years, with a time to extinction for half the planet’s avifauna (ca. 8500 species) of 800–2800 years (Crosby et al., 1996). Although these figures are less pessimistic than other recent estimates derived from less robust data, human pressures on the environment will only increase in the foreseeable future, so these extinction rates will probably prove much too conservative.

B. Globally Threatened Birds: Regions, Countries, Habitats

The majority of threatened bird species occur in Asia and the New World, with relatively few in Africa. The top ten countries for the highest numbers of threatened species are Indonesia (104), Brazil (103), Philippines and China (both 86), India (72), Colombia (62), Peru (60), Ecuador (50), United States (46), and Vietnam (45). Asian countries predominate in this list; the United States ranks high because of its Pacific territories. The highest African countries, ranking 21st and 22nd, are Tanzania (30) and Madagascar (28).

Priority countries might be selected on this basis,
but several further filters can be applied. Because species in the higher categories of threat are likely to become extinct sooner, a reranking involving just those 403 species that are either Critically Endangered or Endangered yields a top ten of Brazil (47), Philippines (45), Colombia (31), United States (25), Indonesia and Mexico (20 each), Peru (18), and Vietnam, Ecuador, and Argentina (16 each). Using this category, the emphasis shifts dramatically to the New World.

A further filter involves only those species from the preceding analysis that are nationally endemic, thereby indicating the degree of “ultimate responsibility” that falls to these countries as their most urgent bird conservation tasks. The Philippines (40) emerge far ahead of Brazil (32), itself far ahead of Colombia (24), United States (17), Mexico (13), Indonesia and New Zealand (12 each), Australia (11), Madagascar (10), and Peru (9). Although it was fairly obvious from the first analysis, given their small land area, that the Philippines would be a priority area, this refined analysis offers startling evidence of the critical importance of the country in terms of avian biodiversity and its impending loss.

The catastrophic erasure of forests from the planet in the course of the twentieth century means that most threatened birds are (mostly tropical) forest dwellers; the only surprising thing is that the figure is as low as 65%. Wetland species account for 9%, scrubland for another 9%, and grassland for 6%. The relatively low forest representation can be explained in part by the fact that the largest tracts of forest, in Amazonia, the Congo basin, and Borneo, are—despite the destruction visited upon them—still too extensive, and the species they contain too widespread, to have resulted in more than a handful of listings from these areas.

C. Causes of Endangerment in Birds

Endangered birds suffer from a range of different threats. Some 52% of them are affected by habitat loss and degradation (although this figure is almost certainly higher, indeed, low-level and hence unreported habitat loss could probably safely be indicated for the other 48%); this theme is explored in the following paragraphs. The next most important threat is simply restriction of range or population, involving 23% of all threatened birds. Hunting afflicts 8%, introduced species 6%, and trade 3%.

Until recently the notion that habitat loss was important in the demise of the Passenger Pigeon (Ectopistes migratorius) had not been entertained, but Bucher (1992) showed how the species was a specialist on seeds produced in masting events whose scale and geographic location varied from year to year, that is, that were patchy in both space and time. Human settlement of the east and center of the North American continent fragmented the native forests to the point where the lapse in both time and distance between masting events simply became too great. Despite the settlers' prodigious slaughter of birds, which has always been blamed for their disappearance, it appears that it may have been their axes, not their guns, that caused the loss of their quarry; the last wild birds very possibly starved to death.

An equally celebrated North American species, perhaps still extant, is the Eskimo Curlew (Numenius borealis), which, like the Passenger Pigeon, used to be hunted in phenomenal numbers in the nineteenth century and likewise never recovered after the slaughter finally abated. It seems likely, however, that the loss of its Argentine grassland wintering grounds and North American prairie spring stopover sites was to blame.

Loss of stopover habitat is beginning to supplant hunting (never a convincing case) as the best explanation for the virtual disappearance of the closely related Slender-billed Curlew (N. tenuirostris), which breeds in western Siberia and migrates southwest to the Mediterranean basin, almost certainly using the once extensive east–west Russian steppes along the way.

Other notable examples of this space/time vulnerability include the Thick-billed Parrot (Rhynchopsitta pachyrhyncha), Purple-winged Ground-dove (Claravis go-dejuna), Andean (Phoenicoparrus andinus), and Puna Flamingos (P. jamesi), Lesser Florican (Sypheotides inalica), and Resplendent Quetzal (Pharomachrus mocinno). The parrot shows the same trait as the Passenger Pigeon, since it is dependent on pine seed, a notoriously unpredictable resource. The species is nomadic, but as its native pine forests in Mexico's Sierra Madre are further fragmented, there is a serious danger that a cone-crop failure will leave the last populations “stranded” too far from food for any to survive. The ground-dove specializes on the seeds of forest bamboo in southeast Brazil. So much forest has been destroyed within its range, and bamboo seedset is so temporally patchy, that the species has become one of the rarest in the country.

The flamingos move between lakes in search of an unpredictable resource. The species is nomadic, but as its native pine forests in Mexico’s Sierra Madre are further fragmented, there is a serious danger that a cone-crop failure will leave the last populations “stranded” too far from food for any to survive. The ground-dove specializes on the seeds of forest bamboo in southeast Brazil. So much forest has been destroyed within its range, and bamboo seedset is so temporally patchy, that the species has become one of the rarest in the country.

The flamingos move between lakes in search of appropriate conditions (which shift over time) and are therefore exposed to the possibility that human damage to even a small number of sites may one day leave the species with nowhere to go. The florican selects different grassland sites from year to year in western India, depending on the effects of local rainfall. Grassland is under enormous human pressure in India, and conserving tracts that may be empty of birds for several years at a time is not a simple proposition. Post-breeding
quetzals are now known to make complex short-distance movements to several different areas, so that many more tracts of forest than one or two may be needed to ensure the long-term survival of viable populations of this species.

In Australia, many birds have been affected by human alteration of the natural fire regime. The Paradise Parrot (Psephotus pulcherimus) almost certainly became extinct (it may conceivably survive somewhere) owing to new burning patterns that suited livestock but not the grasses on whose seeds the parrot subsisted. Similar problems affect the food supply of the Golden-shouldered Parrot (P. chrysopsyrargus) and the habitat of the Noisy Scrub-bird (Arrethornis clamosus).

The reason why restriction of range ranks so highly in the list of threats is because any cause of decline is likely to affect the entire species too quickly for human intervention to help. Such species are often restricted to islands, and when those islands are oceanic, the birds have usually evolved in the absence of continental pressures from mammalian predators. As a consequence they are behaviorally and physically adapted in ways that leave them highly vulnerable when continental predators become established within their ranges, through either the direct or indirect agency of humans. These behavioral adaptations are not degenerative.

The Dodo (Raphus cucullatus) was given its name from the Portuguese slang for “stupid,” and indeed is the possessors dearly if less shy creatures have more time to exploit whatever resource is at stake. Nesting in inaccessible places is needlessly expensive if there is no risk in nesting on the ground in the open. Moreover, the relatively stable conditions on tropical islands tend to promote marked K-selected traits (e.g., slow reproductive rates). So the very things that render island birds so vulnerable to aggressive, fast-breeding, continental animals that are entirely tame, or that nest in what to human eyes are ludicrously undefended places, or that have lost the function of their wings are not evolutionary failures. On the contrary, these seemingly disadvantageous attributes are the result of continuing evolutionary pressures. Wings cost energy to carry and maintain, and in the absence of predators they offer no return on the investment in such energy. Shyness costs its possessors dearly if less shy creatures have more time to exploit whatever resource is at stake. Nesting in inaccessible places is needlessly expensive if there is no risk in nesting on the ground in the open. Moreover, the relatively stable conditions on tropical islands tend to promote marked K-selected traits (e.g., slow reproductive rates). So the very things that render island birds so vulnerable to aggressive, fast-breeding, continental animals have actually been selected for through narrower, often intraspecific competition.

Most avian extinctions since 1600 have been on islands (King, in Moors, 1985), and a significant number of threatened birds today are island species. The impact of rats has been and remains massive (see Atkinson, in Moors, 1985): Magenta Petrel (Pterodroma magenta), Zino’s Petrel (P. madrii), Tuamotu Sandpiper (Prosobonia cancellata), Polynesian Ground-dove (Galliminuva erythroptera), Seychelles Paradise-flycatcher (Terpsiphone curvina), and Barosanga Monarch (Pomarea dimidiata) are a few of the Critically Endangered birds whose fate is directly linked to the invasion of their islands by rats. If the cats can also have been introduced, it is not clear which predator is the greater culprit, and these affected species often live on larger islands where very little can be done to help. The New Caledonian Rail (Gallirallus lafresnayi), Cuba’s Zapata Rail (Cyanelmimus crivertii), the Samoan Moorhen (Gallinula sylvestris), and virtually the entire endemic avifauna of Hawaii (the few that it that survives, but notably the honeycreeper, Drepanididae) are good examples of this uncertainty and impotence. Cats alone are responsible for the plight of some species, such as Townsend’s Shearwater (Puffinus auricularis), Socorro Dove (Zenaida graysoni), and the Marquesan Ground-dove (Gallilcomma rubescens). Mongooses, which were often released to devour rats or control snakes, are major threats to species such as Hawaiian Duck (Anas wylieiii) and St. Lucia’s Semper’s Warbler (Leucoptera semperi).

Ancient lakes, like oceanic islands, often harbor endemic faunas and floras that are highly susceptible to exotic introductions. Among the birds, the grebe family Podicepitidae has been particularly hard hit, with the Alaotra Grebe (Tachyhyphus rufolavatus) of Madagascar and Junin Grebe (Podiceps taczanowski) of Peru close to extinction; the Attilan Grebe (Podilymbus gigas) of Guatemala and Colombian Grebe (Podiceps andinus) have already vanished. Linear water bodies may similarly expose certain species to extinction risks from a single event or series of events: Scaly-sided Merger (Mergus squamatus), Brazilian Merger (M. octosetaceus), Wrybill (Anarhynchus frontalis), Rufous-throated Dipper (Cinclus schulzi), and Luzon Water-redstart (Rhynchorus bicolor) are all vulnerable in this way. Moreover, species that concentrate in a small area for even part of their life cycle may be abnormally exposed to danger. For example, the entire world population of Ascension Frigatebird (Fregata aquila) breeds on a single stack smaller than a municipal parking lot. Even birds that are briefly drawn to individual fruiting trees are liable to suffer: as many as 40 Visayan Wreathed Hornbills (Aceros wal- deni) were shot in a single tree over the course of a single day in October, 1997, an event that quite possibly killed 30% of the population.

The foregoing examples represent “spatial” threats. Other threats are better characterized as “temporal,” involving a seemingly innocent event whose conse-
quences cannot be remedied by the time they become apparent. New Zealand’s Kaka (Nestor meridionalis) and Yellowhead (Mohoua ochrocephala) face enormous difficulties now that introduced wasps compete with them for honeydew, an extremely important foodstuff (breeding success in the Kaka is directly correlated with honeydew intake in the previous autumn). The White-headed Duck (Oxyura leucocephala) faces long-term extinction through hybridization with its New World counterpart, the Rudy Duck (O. jamaicensis), which became feral in Britain in the 1960s and is now spreading into its range. In both cases the costs and logistics of eradication are too great to consider.

Sometimes threats come not from exotics but from natives expanding their ranges, often owing to human modifications of habitat. The spread of cowbirds (Molothrus) through the Americas and the Caribbean is particularly worrying. Birds such as Kirtland’s Warbler (Dendroica kirtlandii) and Black-capped Vireo (Vireo atricapillus) need constant-effort programs to reduce cowbird brood-parasitism to tolerable levels. Similarly the spread through the Caribbean of the Pearly-eyed Thrasher (Margarops fuscatus), a nest-hole competitor, has been viewed with alarm by the Puerto Rican Amaz- (Amazona vitata) recovery teams. Analysis of Neotropical data (Collar et al., 1997) shows that the avian families with significantly high numbers of threatened species suffer from particular threats in combination. Thus the parrots (Poicephalidae) have the greatest proportion of threatened birds in any family (28%), closely followed by the curassows and guans (Cracidae, 26%), and then the tinamous (Tinamidae, 13%), still almost double the 8% rate of endangerment in the New World avifauna as a whole. All three families are sensitive to habitat loss; but the parrots also experience intensive trapping for trade purposes, and the tinamous are no less intensively exploited for food. Possession of a distinct economic value within a beleaguered habitat type, particularly one with some (bio-)geographic restriction, confers a strong likelihood of endangerment.

However, there are many endangered birds whose rarity has abidingly obscure causes. Among these are the White-winged Duck (Cairina scutulata, Southeast Asia), Giant Ibis (Pseudibis gigantea, Indochina), Himalayan Mountain-queal (Oxyyysa supersiliosa, India), Boronean Peackock-phantail (Polyplectron schisternacheri, Borneo), Negros Fruit-dove (Ptilinopus arcaus, Ne-gros, Philippines), Blue-headed Lorikeet (Charmosyna tsonopi, Buer, Indonesia), New Caledonian Lorikeet (C. diadema), Forest Owlet (Athene biewitti, India), Liberian Greenbul (Phyllostrepthus leucoplexus), Cone-billed Tana-ger (Conothraupis mevoluca, Brazil), Cherry-throated Tanager (Nemosia rourei, Brazil), Bidadan Maltme (Mul-imbus bidamanesis, southern Nigeria), and Isabella Oriole (Oriolus isabellarius, Luzon, Philippines). All are biffingly rarer—some are known only by a single museum speci-men—than might be inferred from the habitat appar-ently available to them. Unidentified factors must afflict them all, and clearly sometimes natural causes may be in play, particularly unseen ones such as diseases and infestations (see May, in Coulson and Crockford, 1993), which are known to afflict the Iphis Monarch (Pomarea iphis) and Gouldian Finch (Erythura gouldiae). The safest assumption in cases of unexplicable rarity, at least on continents, is that habitat degradation or loss is in some way involved.

IV. APPROACHES TO THE CONSERVATION OF THREATENED BIRDS

A. Research and Synthesis

The primary conservation need of an endangered spe-cies is information. There is a common behavioral trait among academics of ignoring literature much older than 10 years, presumably partly reflecting the assumption that the data contained in such literature are incorpo-rated into more recent work. Often, in fact, the informa-tion has been ignored; sometimes, however, it has been used but, on proper reconsideration, proves to be faulty. There is therefore considerable virtue in seeking out, assembling, and critically evaluating all information re-lating to an endangered species before deciding on the most appropriate remedial or merely investigative ac-tion. Despite the need for speed in cases of species at risk, precipitate intervention can waste hundreds of thousands of dollars and even prejudice attitudes against a species when its real needs are finally recog-nized. For example, captive breeding management for the Philippine Eagle (Pithecophaga jefferyi), a costly long-term, but to date unsuccessful program, appears to have come into being in response to somewhat over-cautious estimates of the bird’s population size.

Recent BirdLife Red Data Books have sought to pre-sent detailed syntheses of relevant data, extending to translations from languages with which biologists may not be familiar, so that a clear picture of a situation can rapidly be considered and the options objectively assessed. However, there are many other examples of the careful construction of evidence in endangered spe-cies management. One of the most notable is the ex-
The conservation of sites at which endangered birds occur, and of the habitat they are known to occupy, is the primary management technique for ensuring their survival. The key tool is the protected area, which for larger sites is usually reflected in law as a national park, indicating the clear public interest of setting aside a major proportion of a country for noneconomic reasons. Smaller areas are often designated as nature reserves, and are frequently considered more as refuges or scientific laboratories for research purposes than as sites with a broader public service, public access can be more difficult than in national parks. However, the size of many national parks is important for conserving viable populations of larger, low-density species. Naturally it is appropriate to seek to save these species where they are sympatric, thereby maximizing the efficiency of the expense. Evaluations such as those by Wege and Long (1995), Stotz et al. (1996), and Stattersfield et al. (1998) provide clear rationales for the targeting of conservation resources in such a way as to secure not just individual species but the key representatives of biogeographic regions.

In general, endangered birds on continents require larger-scale habitat conservation, whereas those on islands need intensive multi-faceted management (aspects of which are treated in Section III,D). The cardinal element in successful site conservation is local support, backed of course by national government. In its work since 1983 to conserve the montane forests of western Cameroon (to which 25 species of bird are endemic, 9 of them threatened), BirdLife International has implemented a major ICDP (integrated conservation and development project) at Mt. Kilum-Ijim to aid local human communities around the mountains, and this has led to a widespread appreciation of the biological value of the forest without generating the kind of hostility that goes with attempting to create strict exclusion zones. The same kind of program operates at Arabuko-Sokoke Forest in Kenya, home to six endangered birds. Other conservation organizations have been using the same fundamental formula—that local people must be made part of the solution, not demonized as part of the problem.

Campaigns to promote interest in and support for species conservation programs are vital elements of those programs. These may take the form of extension work related to ICDP promotion of sustainable use of local resources, or more direct appeals to people to appreciate the unique value of the wildlife in their neighborhood.

B. Site and Habitat Conservation

The conservation of sites at which endangered birds occur, and of the habitat they are known to occupy, is the primary management technique for ensuring their survival. The key tool is the protected area, which for larger sites is usually reflected in law as a national park, indicating the clear public interest of setting aside a major proportion of a country for noneconomic reasons. Smaller areas are often designated as nature or biological reserves, and are frequently considered more as refuges or scientific laboratories for research purposes than as sites with a broader public service, public access can be more difficult than in national parks. However, the size of many national parks is important for conserving viable populations of larger, low-density species. Naturally it is appropriate to seek to save these species where they are sympatric, thereby maximizing the efficiency of the expense. Evaluations such as those by Wege and Long (1995), Stotz et al. (1996), and Stattersfield et al. (1998) provide clear rationales for the targeting of conservation resources in such a way as to secure not just individual species but the key representatives of biogeographic regions.

In general, endangered birds on continents require larger-scale habitat conservation, whereas those on islands need intensive multi-faceted management (aspects of which are treated in Section III,D). The cardinal element in successful site conservation is local support, backed of course by national government. In its work since 1983 to conserve the montane forests of western Cameroon (to which 25 species of bird are endemic, 9 of them threatened), BirdLife International has implemented a major ICDP (integrated conservation and development project) at Mt. Kilum-Ijim to aid local human communities around the mountains, and this has led to a widespread appreciation of the biological value of the forest without generating the kind of hostility that goes with attempting to create strict exclusion zones. The same kind of program operates at Arabuko-Sokoke Forest in Kenya, home to six endangered birds. Other conservation organizations have been using the same fundamental formula—that local people must be made part of the solution, not demonized as part of the problem.

Campaigns to promote interest in and support for species conservation programs are vital elements of those programs. These may take the form of extension work related to ICDP promotion of sustainable use of local resources, or more direct appeals to people to appreciate the unique value of the wildlife in their neighborhood.

C. Trade Controls and International Legislation

Although trade is not a strong factor in the endangerment of birds in general, it is important for a few groups of species, most notably the parrots. The major international instrument for the control of trade is the Washington Convention, universally known as CITES (Convention on International Trade in Endangered Species), which has been in operation since the 1970s. Animals and plants may be registered in three ways: on Appendix I, which essentially prohibits all movement of the species in question; on Appendix II, which prohibits all commercial trade except under license; and on Appendix III, which allows a particular nation to prohibit trade across its borders irrespective of a species’ status elsewhere.

Because of the immense volume of traffic in parrots, and the problem of identification in so diverse a family (around 350 species), all but three species were placed on Appendix II in 1981. This move had the intention if not the effect of giving protection to the more endangered parrots—naturally their rarity increased their desirability among bird-fanciers—which, if listed alone on the Appendix, could easily have been traded indiscriminately under other names without customs officials necessarily being able to identify them. Appendix II species have quotas set by exporting countries, in theory based on data that show the exploitation to be sustainable. Where the evidence suggests that it is not, movement to Appendix I is supposed to bestow immunity.
Curiously—but as a measure of the power that some trade interests can exert—listing on Appendix I can actually stimulate trade (a) while the species is still at the proposal stage for upgrading but also (b) following listing, on the basis of its enhanced rarity value. This happened to the Hyacinth Macaw (Anodorhynchus hyacinthinus), whose rarity in the wild today is primarily a consequence of a trapping blitz in the 1980s. In general, CITES trade controls have some effect, and allow for very useful monitoring of changes in trading fashions over time. However, for truly prized species such as Lear’s Macaw (A. leari) and Spix’s Macaw (Cyanopsitta spixii), both from Brazil, there is little that any control system can do to eliminate smuggling; the financial inducements are simply too strong. The same tends to be true in Indonesia for exquisite songsters like the Straw-headed Bulbul (Pycnonotus sinensis) and good-lookers like the Bali Starling (Leucopar s Rothschildi).

Other important international instruments for endangered birds are the Ramsar Convention (for important wetlands), Bonn Convention (for migratory species), and Berne Convention (for European species). The Convention on Biological Diversity, already mentioned, ought to be the cornerstone of endangered species conservation across the planet, but considerable effort by nongovernmental organizations is needed to ensure the inclusion of global priorities in the national conservation strategies that each party to the convention is obliged to produce and implement.

D. Management Techniques for “Critically Endangered” Birds

1. Habitat Restoration

Major conservation projects almost invariably involve some habitat restoration work. However, for species at the brink of extinction through habitat loss, the emphasis falls more directly on the rapid replanting of food-plants and land areas. Lear’s Macaw appears to be constrained by the availability of licurı palm (Syagrus coronata), many stands of which show no sign of regeneration owing to cattle-grazing; programs have long been planned to establish many new groves within the species’ range. The Cebu Flowerpecker (Dicaeum quadricolor) survives in an area of heavily degraded forest that consists of a mere 3 km²; efforts are under way to reforest adjacent areas within the next 30 years. There is now an emerging discipline of restoration ecology, and it is likely that a great deal of conservation energy in the twenty-first century will be channeled into reconfiguring habitats that were ruined during the twentieth.

2. Control and/or Restriction of Aliens and Natives

Eradication of exotic predators and pests from islands has been pioneered in New Zealand, where several small offshore islands have been rid of various mammals in order both to preserve resident breeding species and to translocate stricken native species from the main islands (Clout and Craig, in Coulson and Crockford, 1995). This painstakingly systematic restoration of islands—mainly involving the elimination of cats, rats, and mustelids—has been essential to the survival of birds such as the Black Petrel (Procellaria parkinsoni) and Kakapo (Strigops habroptilus), and the expertise generated is now being exported to other islands in the Pacific and Indian Oceans.

Researchers on Mauritius recently discovered why the native, Critically Endangered Pink Pigeon (Nesoenas mayeri) and Mauritius Fody (Foudia rubra) have managed to persist in the face of rat predation. These birds now nest almost exclusively in a grove of exotic Cryptomeria japonica, whose bark produces a sticky gum and whose leaves consist of spiny needles, both of which discourage rats from getting at nests. Curiously, then, in rare cases it appears that exotic vegetation can help rather than hinder native species in their struggle against exotic predators; in this instance the planting of more Cryptomeria is clearly called for.

It is not always the case that exotic predators are the problem. In New Zealand, the native Weka (Gallirallus australis) has proved to be a significant influence in depressing the numbers of Little Spotted Kiwi (Apteryx oweni) marooned on Kapiti Island, of Cook’s Petrel (Pterodroma cookii) on Codfish Island (until removed), and of Chatham Oystercatcher (Haematopus charthemensis) on various Chatham islands. On Bermuda, White-tailed Tropicbirds (Phaethon lepturus) outcompete Cahows (Pterodroma caucho) for nests and have to be controlled. As already mentioned, brood-parasitism by cowbirds requires intensive local control efforts to prevent the suppression of breeding success in Kirtland’s Warbler and Black-capped Vireo.

3. Captive Breeding

The role of captive breeding in endangered birds has long been controversial. The prevailing view among conservation biologists is that captive breeding is not a major management tool for endangered birds, and that indeed it can positively distract attention and resources from serious problems that affect the species. The Philippine Eagle has already been mentioned; similarly, cranes and parrots have in the past been launched into
ex situ programs in the mistaken belief that major benefits will result (both species imprint heavily, and parents of which learn survival techniques through observation of their parents, are particularly disadvantaged for return to the wild). Captive breeding has many other drawbacks, notably the particular dangers of disease transmission to wild birds from captive stock (Snyder et al., 1996).

Nevertheless, captive breeding has achieved several outstanding successes. The Northern Bald Ibis (Geronticus eremita) and California Condor (Gymnogyps californianus) both flourish in captivity while efforts to improve environmental conditions in the wild continue. The Lord Howe Rail (Gallirallus sylvicollis) and Guam Rail (G. owstoni), members of a notoriously vulnerable family (since so many rails reached islands in the past and proceeded to lose the power of flight), probably only persist thanks to ex situ regimes. The Socorro Dove (Zenaida graysoni) survives only because a few Californian bird-fanciers took and bred specimens at a time before its native island was overrun by exotic predators. But zoos throughout the world have bred the species (the wild-caught birds flew back to Mexico; the captive-bred ones flew nowhere at all).

There is also a role for veterinarians in intensive in situ management programs, through their expertise in providing appropriate advice on toxicity of nestbox materials, control of nest parasites, composition and secure provision of supplementary foods, disease screening, and minimization in cross-fostering and translocation exercises.

4. Reintroduction and Translocation

The extirpation of a species at a discrete site may have been caused by a short-term or remediable factor, so that restocking with individuals from elsewhere can be undertaken. This is usually relevant or worthwhile only when the species is globally endangered, but whatever the urgency, the endeavor requires careful planning (Black, 1991). A series of feasibility assessments should determine the site’s continuing ecological suitability (the original constraining factors must no longer operate), the threats it faces, the availability of appropriate stock, the socioeconomic implications, and local, national, and international awareness needs. The birds must be in optimal condition, and if captive-bred they should have been reared in disease-free conditions and in such a way as to be behaviorally and genetically fit for independence in nature. Monitoring of the project is crucial, and it should be documented for circulation to other biologists contemplating such efforts.

Bird species that have benefited from well-designed reintroduction programs include the Nene or Hawaiian Goose (Branta sandvicensis), California Condor, Peregrine (Falco peregrinus), and Chatham Islands Snipe (Coenocorypha puillla). Those that have not include Cheer Pheasant (Catras waliwicht) in Margalla Hills, Pakistan (fox predation), Shore Plover on Mangere Island, New Zealand (the birds flew back to South East Island), and Thick-billed Parrots in the United States (the wild-caught birds flew back to Mexico; the captive-bred ones flew nowhere at all).

Translocation to previously unoccupied sites has become a greatly valued technique, if only as a temporary measure while efforts are concentrated on habitat restoration or predator eradication at the native site. Benefits of this approach include Niuafoou Megapode (Megalopelia pachyura), Vint Iorkeets, Kakapo, Guam Rails following captive breeding, Seychelles Magpie-robin (Copsychus sechellarum), and Seychelles Warbler (Acrocephalus seychellenesis). The work done in preparation for the Seychelles Warbler translocations showed that target islands had many times the insect abundance of the host island, Cousin. This was clearly related to the absence of predation pressure on the insect fauna, and—unsurprisingly but still very strikingly—when birds were released onto the target islands they began breeding almost immediately, and very rapidly expanded their numbers. On Cousin the birds had been so packed that they bred only very slowly, with one offspring tending to stay on territory and help at the nest, waiting for a parent to die (Komdeur, 1997). This observation underscores the value of the food resource base in managing endangered birds, and leads to the next point.

5. Supplementary Feeding

The value of increasing food availability for species whose populations need rapid growth seems to have been perceived only relatively recently, perhaps beginning with work on Peregrines (see Temple, 1978). The technique has been adopted for endangered birds on Mauritius, principally with the Mauritius Kestrel (Falco punctatus), for which extra food clearly enhanced reproductive output (Jones et al., in Coulson and Crockford, 1995). New Zealand workers supporting efforts on Mauritius have found the same with the kakapo: normally the species breeds only in response to major masting events, which may occur once every five years, but with dietary supplements it appears to be capable
of breeding every year. On Hokkaido, Red-crowned Cranes (Grus japonensis) have recovered from near-extinction through a combination of better protection and extensive food provision. Clearly, as a relatively short-term measure supplementary feeding can be crucial in producing an unnaturally rapid reproductive output, a very desirable effect in critically low populations where the genetic value of every individual needs to be maximized.

6. Nest-Site Provision or Enhancement
Where nest sites are limiting (often the case with hole-nesting species), the provision of nestboxes or the enhancement of natural cavities may be appropriate. Puerto Rican Amazons ignored the former but benefited from the creation of nesting ledges. The provision of grilles at entrances has helped prevent White-tailed Tropicbirds from appropriating Cahow burrows. In the Galapagos, a new, more secure colony of Dark-rumped Petrels (P. phaeopygia) was established by digging nest burrows and playing calls among them at night.

7. Cross-Fostering and Cross-Breeding
Many large raptors and most cranes lay two eggs but normally rear only one young, so biologists attempting to increase productivity of endangered forms of such birds have long sought to make use of the expendable second eggs by taking them for hatching and captive breeding. In the case of the Whooping Crane (Grus americana), an attempt was made to establish a second population by placing such eggs in the nests of Sandhill Cranes (G. canadensis), but this did not result in a breeding population, possibly as a result of imprinting. The most famous instance of cross-fostering involved the Black Robin (Petronia traversi), whose population fell to five individuals in 1980 but recovered by the placing of some eggs in the nests of Chatham Island Tuft (P. macrocephala).

Cross-breeding with another subspecies was regarded as the last hope of the dusky seaside sparrow (Ammospiza maritimus nigrescens), but the last stock died out before the endeavor could begin. However, it has been used on the endemic Norfolk Island race undulata of the New Zealand boobook (Ninox novaeseelandiae), which by 1986 had been reduced to a single female. After nestboxes were erected to overcome an immediate shortage, two male nominate male boobooks were introduced to the island; one of them paired with the female and in due course produced a string of hybrid offspring. The taxonomic (and legal) implications of this technique may not have been considered, but it clearly represents a means of preserving genetic diversity.

8. The Role of the Concerned Citizen
Finally, it is worth stressing that much of the advocacy for endangered birds, and many of the insights into their plight and salvation, comes from national and international conservation organizations. One of the most valuable things that any sympathetic individual can do to help endangered birds is simply to join or support such organizations. Their conservation effectiveness depends not only on the financial security derived from a broad membership base, but also on being recognized as the representative mouthpieces of a constituency consisting of millions of concerned citizens.

I. Introduction
II. Major Ecosystems at Risk
III. Conservation of Ecosystems

GLOSSARY

biological diversity The variety of genes, species, and ecosystems in the living world.
biome Group of ecosystems with similar characteristics, usually a major vegetation type such as tropical rain forest or grassland.
community All of the populations of organisms that live within a given area.
conservation status Relative likelihood of extinction of a species or community.
deforestation Physical removal of trees and consequent reduction in forest cover.
decoregion Geographic region of similar ecological processes and ecosystems.
ecosystem Community of species and their environment.
endangered Very likely to become extinct within the near future.
edemism Degree to which species are unique to a specific location.

THE SCALE OF HUMAN IMPACT ON THE NATURAL ENVIRONMENT has resulted in the decline and loss of many ecosystems. All of the world’s major biomes are to some degree adversely affected by human activities, with forests, scrub and grasslands, freshwater and coastal ecosystems being the most threatened. Specific ecosystems at risk include dry tropical forests, especially on islands, temperate forests, Mediterranean shrublands, temperate grasslands, and coral reefs. Overall, the large marine and oceanic ecosystems, polar regions, and dry deserts are generally less threatened.

I. INTRODUCTION

In terms of area, there seems little doubt that the recent expansion of mechanized agriculture has been the main factor in a rapid conversion of suitable ecosystems into agricultural production. Large areas of forest, woodland, and grassland have been destroyed following the expansion of agriculture, starting in southwestern Asia, China, the Mediterranean, and Europe.

Many temperate ecosystems, such as forests, woodlands, grasslands, and wetlands, are endangered as a result. Similar trends are now obvious in the tropical regions of the world, exacerbated by poor forestry practices and the replacement of forests with cash crops. Even where natural ecosystems have not been subject...
to deliberate modification, human impacts are detectable as a result of exploitation, pollution, and the presence of foreign species.

Ecosystems can be considered endangered when their extent, species composition, or the natural processes that sustain life become sufficiently disrupted or degraded. The difficulty in describing the exact extent and status of an ecosystem, however, makes the assessment of their conservation status much more difficult than it is for a species of organism. In particular, the conservation status of an ecosystem depends greatly on the scale at which the ecosystem is considered. From the major global biomes such as tropical forests, or deserts, to the regional and local scale, various threats operate that affect the likely persistence of that ecosystem, or its components. The ecoregional approach offers good potential for classifying, assessing, and managing ecosystems at the regional scale—combining environmental and geographic attributes to identify specific regions of high biodiversity.

Efforts to conserve ecosystems are being made throughout the world, but these are often hampered by conflicting land-use issues and a general lack of understanding of ecosystem processes. At the global level, international conventions and agreements have established a legal framework for ecosystem conservation. Several countries have begun the task of classifying ecosystems and determining threats. The conservation of natural ecosystems will require coordinated action at a variety of levels, from international to local, and will require a fundamental change in the patterns of resource exploitation and consumption.

A. Definition of an Ecosystem

Nearly sixty years after the development of the concept of an ecosystem, it is now apparent that many have been lost through human activities, or so significantly altered that they may be considered endangered. Our understanding of ecosystems has changed profoundly, with much greater recognition now given to their dynamic and complex nature and the potential for human activities to change their biological and physical components.

The International Convention on Biological Diversity, developed prior to the United Nations Conference on Environment and Development held in 1992, defines an ecosystem as “a dynamic complex of plant, animal and micro-organism communities and their non-living environment interacting as a functional unit.” By itself, however, the term ‘ecosystem’ does not connote any specific dimensions and the boundaries of ecosystems are often indistinct. Even in aquatic ecosystems, where the presence of water helps to identify the lateral boundaries of lakes and rivers, the extent of an aquatic ecosystem will fluctuate with changing water levels, floods, and tides. In the marine environment, ecosystems may be defined by particular attributes of water temperature or chemistry, or by the characteristics of the substrate, in addition to specific plant communities (e.g., seagrass beds or kelp forests). Other ecosystems may be defined by specific geographic or special physical characteristics, such as caves or sea-mounts.

The uncertainty in defining the exact extent of an ecosystem has hampered attempts to quantify their conservation status. Ecosystems can be increasingly finely described and there is no consensus on which level is the most appropriate for conservation. At the broadest level, ecosystems cross international boundaries and are subject to a wide range of threats and human influences. These major ecosystem types can be sub-divided, as they vary enormously in their biotic composition, environment, and functioning, often as a result of major geographic features such as mountain ranges, bays, and river catchments. At a fine level, an ecosystem may comprise a small group of underwater cave systems, sand dunes, an isolated island and fringing coral reef, or a mossy high-altitude swamp that covers no more than a few hectares.

The concept of an endangered ecosystem is relatively new compared to the widely accepted concept of an endangered species. The World Conservation Union (IUCN) has maintained an internationally recognized system of “Red Data Books” (e.g., Walter and Gillett, 1998) for defining and listing threatened species for many years, but no universally applied system has been developed for ecosystems. Similarly, there is no recognized system for measuring the relative conservation status of an ecosystem and it is often not clear in what sense the whole of the ecosystem can be seen to be threatened, especially if many of the resident and visible animals and plants remain reasonably abundant. While it is clear in most cases at what point a species has become extinct, it is much less clear at what point a specific ecosystem ceases to exist.

A paucity of information on many ecosystems, as well as the lack of a standard approach, has hampered attempts at national or global assessments of conservation status. The European Environment Agency assessment (Stanners and Bourdeau, 1993), for example, found that incomplete and fragmented data made it impossible to prepare a complete and systematic assessment of Europe’s ecosystems. Information about nature conservation at the international level was found to be
focused largely on protected areas only and frequently did not cover parameters such as habitat types, human pressures, or type of management that might be important in determining their status.

B. Overviews of Endangered Ecosystems

1. General Reviews

Despite the various problems and general lack of knowledge, there have been several attempts to provide an overview of the conservation status of the world’s ecosystems. The most notable of these overviews have been compiled by the World Conservation Monitoring Centre (e.g., WCMC, 1992) and the United Nations Environment Programme (UNEP) (e.g., Heywood, 1995). Regional assessments of varying thoroughness have been completed for Europe (Stanners and Bourdeau, 1995), United States (Noss and Peters, 1995), and the Asia and Pacific regions (UNESCAP/Asian Development Bank, 1995). Reviews of particular ecosystem types have been completed by a number of agencies. The United Nations Food and Agriculture Organisation, for example, produces a regular update of forest ecosystems (e.g., FAO, 1997), and some coverage of grasslands and other drier ecosystems is provided by UNEP (e.g., Middleton and Thomas, 1997). Marine ecosystems subject to review include mangroves and coral reefs (World Resources Institute, 1996) and oceans (IUCN, 1991). A number of regional freshwater ecosystem reviews have been completed (e.g., Dugan, 1993), and wetland conservation databases are maintained by Wetlands International, World Resources Institute, and other agencies.

2. Endangered Ecosystems in the United States

As one of the most extensively cleared and developed of the world’s large countries, the United States has experienced a dramatic decline in the extent of many ecosystems in the past few hundred years. Using the decline in extent of major vegetation associations, Grossman et al. (1994) described some 371 globally rare terrestrial and wetland plant communities in the United States. Another 482 communities required further definition before they could be mapped and ranked with certainty. Noss and Peters (1995) used this system to identify hundreds of threatened ecosystems. They based their assessment on four factors—if the ecosystems have been greatly reduced since European settlement, if they are currently very small in extent, if they have a number of threatened species, and/or if the continued threat to their existence is high. The greatest reduction in extent has occurred in the prairies and other grasslands, savannas (such as the oak savannas in the Midwest), and some forest and wetland ecosystems. Twenty-seven ecosystem types have lost more than 98% of their original extent, including spruce–fir forest in the southwest Appalachians, pine rockland habitat in south Florida, and mesic coastal prairies in Louisiana, sedge meadows in Wisconsin, and Palouse prairies in the Pacific Northwest (Table 1).

3. Endangered Ecosystems of Australia

In Australia, several studies have also attempted to identify endangered ecosystems, particularly in relation to forests subject to commercial logging operations. The most extensive of these inventories has been carried out as part of the Regional Forest Agreement (RFA) process, which is a national effort to create a system of protected areas within regional forest management plans across Australia’s major commercial forest areas. The RFA process defined an endangered forest ecosystem as one “where its distribution has contracted to less than 10% of its former range or the total area has contracted to less than 10% of its former area, or where

90% of its area is in small patches which are subject to threatening processes and unlikely to persist.” These studies have resulted in the identification and subsequent protection of many endangered forest ecosystems. Although these efforts have not resolved all outstanding issues relating to forest conservation, or adequately protected all forest types, it has been clear that a rigorous definition and assessment process is a prerequisite for successful conservation of these ecosystems.

A major study has also been undertaken to identify threatened ecosystems in the south-west corner of Western Australia—an area of extremely high plant diversity. Based on a modification of the Conservation Status categories adopted by the IUCN/World Conservation Union (e.g., Walter and Gillett, 1998), the study is one of the first attempts to carry out a scientifically rigorous and repeatable assessment of the status of ecosystems, referred to in the report as “ecological communities.” Criteria are established for each of the IUCN categories: Presumed Extinct (modified to Presumed Totally Destroyed), Critically Endangered, Endangered, Vulnerable, Data Deficient, and Lower Risk. As with the species categories, each ecosystem is assessed against a set of modified criteria relating to the degree to which the original extent of the ecosystem has been reduced, the number of occurrences of the ecosystem and the extent to which it is restricted or isolated, and the degree to which the ecosystem has been modified and could be rehabilitated or restored. A total of 110 ecological communities were identified as being possibly threatened. Sixteen communities were found to be Critically Endangered, 7 as Endangered, 10 as Vulnerable, and 3 as Data Deficient. The most severely threatened ecosystems tended to be forest, woodland, and shrubland communities restricted to specific soil types, and the wetlands associated with these communities.

As with the Regional Forest Agreement process, this approach allows for a more meaningful assessment and, importantly, allows conservation targets to be established as part of the management of the ecosystem. Efforts to define and identify endangered ecosystems have also been advanced by the adoption of national endangered species conservation legislation in Australia (the Endangered Species Protection Act of 1992), which includes a legal definition for endangered ecosystems. Under this legislation, specific ecosystems can be identified and listed on appropriate schedules and guidelines have been established for the assessment of status. Importantly, the legislation recognizes that ecosystems are defined not only by their boundaries and extent, but also by the identity and number of species (structure) and the interactions that link species and their environment (processes).

Box 1

1. Community may already be extinct.
2. Community is subject to current and continuing threats likely to lead to extinction as demonstrated by one or more of:
   (a) Marked decrease in geographic distribution.
   (b) Marked alteration of community structure.
   (c) Loss or decline of native species that are believed to play a major role in the community.
   (d) Restricted geographic distribution such that the community could be lost rapidly by the action of a threatening process.
   (e) Community processes being altered to the extent that a marked alteration of community structure will occur.

C. The Ecoregion Approach

In recognition of the difficulty involved in describing and measuring the status of ecosystems, an approach based on the combination of environmentally and geographically similar features into “ecoregions” has been developed. Olson and Dinerstein (1998) used this approach to identify some 200 of the world’s most significant ecoregions by assessing the number of species and levels of endemism they contained. The advantage of such an approach is that it allows a reasonably precise area to be defined, some level of risk to be determined in relation to the various biological components, and a reasonable basis for comparison, at least for terrestrial ecosystems. Given the dynamic nature of ecosystems, and the fact that they are as much a result of interactions between species as they are of a particular locality, it probably makes more sense to use the ecoregion concept as a basis for comparing conservation status. Much
of the overview of endangered ecosystems in this article is therefore based on the ecoregion concept.

II. MAJOR ECOSYSTEMS AT RISK

A. Forests

1. General Status

It is variously estimated that between 1700 and 1980, the total area of all land remaining in a natural state decreased by more than one-third, from about 95% to about 69%, mostly as a result of expanding human populations and agriculture. In densely populated subregions, such as the western part of Europe and southern China, this level of conversion has been much greater, with less than 30% now remaining. The large-scale loss of ecosystems resulting from human influence can be seen most readily with the conversion of fertile temperate forests for cropland and pasture. Considerable decline in forest area had already taken place by 1700, especially in the Mediterranean Basin and the Indus Valley (areas occupied by ancient Egyptian, Indian, Greek, and Roman civilizations) and in northern and northwestern China. Large declines also occurred in northwestern Europe during the Middle Ages. Primary or old-growth forest (more than 200 years old) is now only a small part of the world’s total forest area. Primary forest cover has been greatly reduced in most industrial countries and is rapidly decreasing in less-developed ones.

In contrast to the Mediterranean region, development in North America did not lead to the almost complete loss of forest. Over some 130 years, an initial rapid conversion of forested land was followed by a slowing down in clearance rates, and eventually by a stabilization. In Australia, some 47% of all forests were cleared over the last 200 years, but mostly during the period of rapid economic expansion after the end of the Second World War. A similar pattern of forest loss is now occurring in the developing (mostly tropical) world. These patterns are again fueled by expanding human populations and agriculture, with the added impetus of industrial crops such as rubber and oil palm.

2. Major Threats to Forests

Deforestation is a serious problem throughout the world’s major forest areas, although its causes and magnitude vary by region. In Africa, for example, the major cause of deforestation is forest clearance for agriculture (particularly commercial farming and to some extent shifting cultivation) and the harvesting of fuelwood. Commercial logging is limited, but settlement and agriculture around roads built to transport timber have resulted in additional clearing of forest areas. The total area of tropical forests in Africa in 1990 was estimated to be approximately 330 million hectares (ha), compared with 369 million ha in 1980, a loss of nearly 7%. The remaining forests in humid West Africa are disappearing at the rate of about 2% a year, and exceeding 5% in the extreme case of Côte d’Ivoire. The relic blocks of forests left at Gola in Sierra Leone, at Sapo in Liberia, and at Tai in Côte d’Ivoire are now of global importance as the last significant remains of the structurally complex and species-rich forests of the upper Guinea zone. Some areas, such as Fouta Djallon, Mount Nimba, and Loma at the head of major water-sheds in western Africa (the Niger, Senegal, and Gambia Rivers), harbor exceptional biodiversity.

Similarly in Latin America, deforestation is due mainly to the expansion of agriculture. This process is driven by a number of factors, the most important being the displacement of peasant farmers from traditional farming areas, large-scale settlement programs such as in Rondonia in Brazil, and the deliberate promotion of livestock-raising activities in the Amazon through financial incentives. In addition, commercial logging, collection of firewood for household use, and road construction have all led to the unsustainable exploitation of the region’s forests. Deforestation has been most severe on the Pacific coast of Central America, where less than 2% of the original 530,000 square kilometers remains, and within the Atlantic forests of Brazil, which now has only 4% of its original 1 million km² as pristine forests. The rapid loss of highly diverse native forests is of particular concern, because they are often replaced by species-poor pastures or by monocultures of exotic timber species. Most of the endangered tropical plants in Brazil (65%) are found in this highly endangered tropical forest ecosystem.

In the Asia and Pacific regions, three countries—Australia, Indonesia, and China—account for 52% of the remaining forest cover. As a result of industrialization, agricultural expansion, and poor forestry practices in many countries, deforestation is one of the major environmental issues in the region. Various agencies, such as the FAO, report that deforestation in the region increased from 2 million ha per year during 1976–1981 to 3.9 million ha per year in 1981–1990, with Bangladesh, Pakistan, the Philippines, and Thailand experiencing the fastest rate of forest clearance. The Pacific subregion has the lowest rate of deforestation (around 130,000 ha per year), most of which occurs in Papua.
New Guinea. Rapid population growth has contributed to depletion of forests not only through land clearing for cultivation but also through over-harvesting of forests for fuelwood, roundwood, and fodder. At the current rate of harvesting, the remaining timber reserves in Asia may not last for more than 40 years.

Although the extent of forest cover in Europe may be significant and stable, or even increasing in parts, many of the elements of the forest ecosystem have been severely modified or lost and for this reason are considered to be threatened. Mature natural forest ecosystems are very rare. In northern and central Europe this rarity has been caused primarily by intensive logging, resulting in a significant decrease in the integrity and natural condition of forests. Forests have been modified significantly to increase their commercial value at the expense of natural ecosystem complexity and structure. They are more likely to contain uniform, relatively even-aged stands, with little dead timber, and with a significantly reduced complement of animal species. In addition, there has been extensive use of nonnative species such as Sitka spruce (Picea sitchensis) in the north and eucalyptus (Eucalyptus spp.) in the south.

The Mediterranean forests have lost much of their natural condition as a result of excessive logging, fire, and overgrazing by livestock, especially goats. Forests are especially threatened at the boundaries of their natural distribution, such as the forest-steppe regions of southern Ukraine and Russia or in the Mediterranean Basin. Most of central Europe’s alluvial forests along all major river courses have virtually disappeared. Airborne pollution (mostly in the form of acid deposition and photochemical smog) is also a major cause of damage to forest ecosystems in Europe, particularly in central and eastern Europe. First reported in the Black and Bavarian forests of Germany in the early 1970s, damage from air pollution may now be detected in a quarter of all European trees.

One of the growing threats to particular forest ecosystems stems from the vast increases in tourism to remote and spectacular regions such as the Himalayas. The fragile high-altitude ecosystems of the Annapurna Himal, Nepal’s most densely populated and ethnically diverse region, have been badly affected by a boom in tourist numbers. To provide trekkers with hot food and showers, the lodges in a single village are obliged to cut one hectare of virgin rhododendron forest each year. Throughout Nepal, about 400,000 ha of forest are cleared each year—an annual loss of 3% of its forests. Between 1975 and 1980, 13% of Nepal’s forests were destroyed. Moreover, each hectare of logged forest results in the erosion of anywhere from 30 to 75 metric tons of soil annually.

3. Endangered Forest Ecosystems

Table II shows examples of some of the most endangered and biologically diverse forest ecosystems in the world. It is clear from this table that many tropical moist forests are endangered, particularly forests in western Africa, the lowland forests of Southeast Asia, and forests on islands such as Madagascar and the Philippines. Rapid development of these regions for agriculture and large-scale commercial logging have been primarily responsible for this extensive forest loss. Large-scale fire now poses a major problem in some of the previously contiguous forests of Indonesia and Malaysia, especially during periods of prolonged drought.

Similar problems face the seasonally dry forests, especially the monsoon forests and conifer forests in the tropical and subtropical regions of the world, especially because these are often more restricted in their original distribution. The forests of Madagascar are of particular concern, as are the dry tropical forests of Central and South America, both of which are biologically distinct and now much reduced. The remaining dry forests of Madagascar represent some of the richest dry forest ecosystems in the world in terms of their natural diversity. Around 165 million years ago, Madagascar drifted away from Africa, which allowed its native species to evolve in isolation from the mainland continent. Among the many unique species are the lemurs—members of the primate family found only on Madagascar and the neighboring Comoros Islands—including the recently discovered mouse lemur (Microcebus myoxinus) and golden-crowned sifaka (Propithecus satraxis), both of which appear to be restricted to this ecosystem. Temperate forests have also been extensively cleared for hundreds of years and few large intact examples remain. Forest loss has been most severe in western Europe, and most examples of this forest type are now restricted to central and eastern Europe. Clearing has also proceeded apace in the temperate forests of China and around the Himalayan region in the past few decades. Most examples of temperate rain forests, including the southern temperate beech forests (Nothofagus spp.) of Chile and New Zealand, are now much reduced in extent.

The Caucasus ecoregion harbors some of the most diverse and distinctive temperate conifer and broadleaf forests in Eurasia, as well as rich woodlands, steppe, and grasslands. One of the world’s seven temperate rain forests formerly occurred here, but this habitat has been

virtually destroyed. Lowland forests are dominated by oak, chestnut, and lime, while higher regions are covered by beech, fir, and spruce. Although the ecoregion covers a relatively small area, its varied range of landscapes and climates, and its geographic position at the edge of Europe and Asia, has given the ecoregion a high level of biological diversity, with many European and Asian species represented. In the Caucasus Mountains alone, more than 6000 species of vascular plants have been recorded (of which 20% are endemic), as well as...
B. Scrub, Heath, and Grasslands

1. General Status

Despite their often uniform appearance, low-stature vegetation communities of the type referred to as scrub, heaths, and grasslands are complex and varied, with many regional variations and subtle differences resulting from soil type and climate. They are usually present where soil nutrients, water availability, or climate are not conducive to the growth of forests. They are well suited, however, to grazing by domestic animals and for conversion to cultivation, especially cereal crops. As a result of their suitability for agricultural development, temperate scrub, heaths, and grasslands are among the most modified of the world’s major biomes.

Large areas of current and former temperate scrub and grasslands occur throughout continental Europe and Asia and North America. Significant areas also occur in the Southern Hemisphere, in southern Australia, southern Africa, and temperate South America. In northern polar regions, these communities extend into the Arctic Circle, forming a vast patchwork of semi-frozen and permanently frozen swamps and low vegetation. This latter region appears to be relatively intact, although the future impacts of global warming might considerably alter the distribution and extent of these ecosystems.

European communities of this type range from the Arctic tundra to the Mediterranean shrublands, including many different types of woody shrub communities (including maquis and dwarf shrub heaths), tall herb stands, and many types of grassland. They occur at all altitudes and can range from very sparse to very dense cover, and from a few centimeters to 2 or 3 m in height. Human activities have modified most European scrub and grassland plant communities other than those found on mountain tops or on very poor soils. In some cases, particularly where wetland drainage or forest clearance for timber and farming has taken place, new scrub and grassland ecosystems have been created on lands that were previously wetland or forest.

Closer to the tropics, vast areas of tropical savannas and grasslands can still be found in Africa, Australia, and South America. Large parts of these savannas are used for pastoralism, and the impact of large numbers of grazing animals, often poor soils, changed fire regimes, and human settlements have modified and degraded many areas. As native vegetation cover declines, soil erosion proceeds and turns these semi-arid ecosystems into deserts.

In both hot and cold regions, lack of water typically creates heathlike low scrub, sparse grassland, and desert communities (with characteristic species such as cacti and other succulents), many with a high level of endemism and species richness. Large areas have been cleared for cultivation in North America, Australia, and Europe in regions where rainfall is reasonably predictable.

2. Endangered Scrub, Heath, and Grassland Ecosystems

Table III shows some of the most endangered and biologically diverse ecosystems of this type in the world. Many temperate ecosystems have been lost or so extensively modified that it is difficult to determine their original nature. In Australia, for example, less than 1% of the original temperate lowland grasslands remain, much of this restricted to road sides, railway lines, cemeteries, and lightly grazed unimproved pastures. Some of the world’s most floristically diverse regions, such as the mixed shrublands of the Mediterranean, South Africa, and southwestern Australia are now highly fragmented and suffering from impacts such as dryland salinity and more frequent or intense fires.

Given their suitability for grazing animals and agriculture, it is not surprising that large areas of grasslands have been converted from their natural state. In eastern

8300 species of ferns and 1200 types of lichens and mosses.

The endangered temperate forests found in southern China are also among the world’s most biodiverse temperate regions. Subtropical evergreen broadleaf forest is the dominant vegetation of this ecoregion, which also includes alpine ecosystems, steppe grasslands, and wetlands. Alpine vegetation of the Qinghai–Tibet plateau predominates in the west and the higher regions of the Hengduan Mountains of the southwest. Deciduous broad-leaved forests of the warm temperate zone occur north of the province. Though the biological richness of China and Sichuan is well recognized, international attention has largely focused on a single species that has become a symbol for conservation efforts worldwide—the giant panda (Ailuropoda melanoleuca). Sichuan province is home to the vast majority of the world’s wild pandas. Loss of vegetation cover is one of the main threats to wildlife in the province and half of its panda’s habitat (10,000 km²) was lost between 1974 and 1989 alone. Logging and small-scale agriculture have been converted from their natural state. In eastern

In both hot and cold regions, lack of water typically creates heathlike low scrub, sparse grassland, and desert communities (with characteristic species such as cacti and other succulents), many with a high level of endemism and species richness. Large areas have been cleared for cultivation in North America, Australia, and Europe in regions where rainfall is reasonably predictable.

Large areas have been cleared for cultivation in North America, Australia, and Europe in regions where rainfall is reasonably predictable.
Europe the steppe ecosystems have become extremely rare and large areas of undisturbed steppes are now found only in the south, where they border semidesert regions (north and west of the Caspian Sea, i.e., the Volga Delta and Terek region). The principal cause for the loss of scrub and grassland habitats over the last 50 years has been the advent of widespread agricultural mechanization, which has resulted in the cultivation of large areas of natural and semi-natural grassland. Remaining grasslands are isolated and highly fragmented, and usually restricted to steep slopes and ground with thin soils. Increased use of fertilizers and biocides has further threatened many species. The vast grassy plains of North America have been drastically reduced. The tallgrass prairies of the American Midwest and Great Plains are a unique set of plant communities that once covered vast areas of the continent and supported huge herds of grazing animals such as the bison. Originally thought to be poor agricultural lands, because of the scarcity of trees, the prairie ecosystem was discovered to be immensely fertile, and during the period from the early 1800s to 1930, about 90% of this ecosystem was converted to farmland.

One of the most biologically diverse and endangered of all the world's ecosystems are the fynbos shrublands of the southwestern and southern Cape of South Africa. Although relatively small in extent, the 470 km² of the Cape Peninsula, including Table Mountain, are home to 2236 different plant species, including one of the highest concentrations of endangered plant species. The fynbos is under serious threat from increasing urban expansion (especially in the Cape Flats area) and invasion by exotic weed species, including a number of Australian acacias. Similar shrubland communities can be found along the coastlines of the Mediterranean, southwestern Australia, southern California, and Chile, and in each case they are considered to be threatened.

C. Wetlands

1. General Status

The term "wetland" covers a variety of inland, coastal, and marine habitats that are temporarily or permanently under water. The convention for wetlands of international importance (the Ramsar Convention) defines wetlands as "areas of marsh, fen, peatland or water whether natural or artificial, permanent or temporary, with water that is static or flowing, fresh, brackish or salt, including areas of marine water the depth of which at low tide does not exceed six metres." With such a wide definition and range of ecosystems classified as...
wetlands, and the dynamic nature of floods, tides, and rainfall, it is difficult to accurately gauge the total extent of wetland ecosystems or to precisely define their location. Nevertheless, there have been a number of attempts to classify the world’s wetlands and to provide an overview of their extent and status at the regional level (e.g., Scott and Poole, 1989; WCMC, 1992). In 1971, the Ramsar Convention was signed in the small Iranian town of Ramsar to protect wetlands and promote their “wise use.” Acceptance of the convention has since grown and most countries are now signatories. The existence of the International Wetlands Convention (as it is also known) has resulted in the development of a catalog of many of the world’s most significant wetlands. In addition, the Convention allows the recording of “sites where changes in ecological character have occurred, are occurring or are likely to occur”—the Montreux Record. By 1998, 61 sites were listed on the Montreux Record, including the Florida Everglades (United States), Chilika Lake (India), and the 400,000-ha Shadegan Marshes and mudflats of Khor al Amaya and Khor Musa in Iran.

2. European Wetlands

Given the long agricultural and industrial history of Europe and the Mediterranean region, it is not surprising that most of its wetlands have been significantly modified or lost. Only in the extreme north do large wetland ecosystems remain relatively intact. Of the more than 300 European and Mediterranean wetlands of international importance designated in the Ramsar Convention, 80% are considered to be threatened to some extent. Of major concern has been the continued loss and degradation of freshwater habitats in the Mediterranean Basin, including many inland lakes and coastal lagoons and estuaries. In Spain alone, more than 60% of all inland freshwater wetlands have disappeared during the last 25 years.

The major threats to wetland ecosystems in this region result from human activities, most notably the diversion of water supplies for industry and agriculture, drainage for urban expansion and grazing, and more recently pollution from industrial sources. The use of lake and river water for industrial purposes often affects water quantity (when abstracting water) and water quality (when reintroducing it as wastewater, sometimes polluted or of higher temperature). Many industries, such as pulp and paper production and mining, wash large quantities of particulate matter into lakes and rivers.

The harmful increase in nutrient levels (eutrophication) occurs widely where the catchments of lakes and other wetlands are intensively farmed or densely populated. Fish-farming operations and sewage effluent discharge may also result in the eutrophication of water bodies. As a result of increased nutrient levels (most commonly nitrogen- and phosphate-based fertilizers or animal and human wastes), there is an increase in phytoplankton production and microbial decay with consequent deoxygenation of the water and production of toxins.

The Aral Sea of southwestern Asia is one of the most threatened wetland ecosystems in the world, and will require major international effort and cooperation to restore it to a reasonable state of health. The Aral Sea is fed by the Amu Darya and Syr Darya Rivers, flowing from the mountains of Tian Shan and Pamirs. These waters are the main source of water for Uzbekistan, Kyrgyzstan, Tajikistan, Turkmenistan, and the southern part of Kazakhstan. Traditionally, about half of the water was used for irrigation and the other half flowed into the Aral Sea. Intensive development of cotton and other irrigated crops over the last few decades has reduced the inflow of these rivers to about 3% of former levels. Since 1960 the Aral Sea has lost two-thirds of its volume and its salinity level is now approaching that of seawater. Almost all the native organisms have died out. The 3.3 million ha of exposed seabed have become a source of wind-borne salt and agricultural residues that now spread over surrounding areas. The five republics developed a water distribution agreement in 1992 and an Aral Sea Programme in 1995, which aims to stabilize the region and improve the management of the waters in the basin.

In some cases, the source of wetland pollution may be distant, with contaminants being transported through the air in the form of industrial emissions. One of the best-known examples of this threat to wetland ecosystems was the acidification of European rivers and lakes, especially in the southern parts of Scandinavia. During the 1950s and 1960s, at the peak of sulfur deposition, the rate of acidification was several hundred times that of the natural process and thousands of Scandinavian lakes became too acidic to support their original fish populations. Despite a decline in atmospheric pollution over the last two decades and partial mitigation through liming activities, acidification continues to have detrimental effects on these lake ecosystems.

Marshes, bogs, and fens are a group of vegetated wetlands that were once widespread in Europe. Since early medieval times, however, these habitats have been drained or mined for peat. Though some extensive areas of peatlands and similar ecosystems still exist in the
waters of Florida Bay with silt, which now threatens to blooms have contaminated much of the previously clear a half-century ago. Seagrass die-offs and massive algal glades have shrunk to a tiny fraction of what they were in wading bird populations by some 90%, and the Everglades have been managed successfully and there has been a deal to restore environmental quality. Nutrient levels have been managed successfully and there has been a decline in the concentrations of some toxic chemicals such as persistent organic pollutants derived from pesticides and industrial processes. The flora and fauna of Lake Superior have recovered and are again in good condition. The system remains in a fragile balance, however, and concentrations of many toxic chemicals remain high. Aquatic habitats and wetlands are still in a poor state overall, and the aquatic ecosystems of Lakes Michigan, Ontario, and eastern Erie remain highly modified.

Equally famous are the Everglades of the U.S. Southeast—the largest example of a rare flooded grassland ecosystem. For the past 30 years, south Florida has experienced an accelerated loss of this large and unusual wetland complex. From the Kissimme River, a series of marshy oxbow lakes flow into Lake Okeechobee, one of America's largest freshwater lakes. Okeechobee in turn feeds slowly into the Everglades itself, known as the fabled “River of Grass.” To the south, the shallow estuary of Florida Bay once contained a very rich marine life, and an extensive coral reef system thrived off the Florida Keys. Excessive consumption of water for agriculture and residential populations has led to a decline in wading bird populations by some 90%, and the Everglades have shrunk to a tiny fraction of what they were a half-century ago. Seagrass die-offs and massive algal blooms have contaminated much of the previously clear waters of Florida Bay with silt, which now threatens to

6. Wetlands of Asia

Some of the most thorough reviews of threatened wetlands have been carried out by nongovernmental organizations in East Asia, such as Wetlands International (e.g., Scott and Poole, 1989). Over half of the wetlands of international importance in Asia show a moderate to high degree of threat, with the largest number of threatened sites occurring in China, India, Indonesia, Malaysia, Pakistan, the Philippines, and Sri Lanka.
Hunting and human disturbance are significant threats to wetlands in Asia, as are human settlements, drainage for agriculture, pollution, fishing, and logging.

The rivers, lakes, and other freshwater habitats of the lowland Sundas region (western Indonesia, Malaysia, and Brunei) contain the most significant freshwater diversity of any Asian wetland ecosystem. Forest loss is by far the most serious threat to these freshwater ecosystems as it disrupts the flow of nutrients, leads to water temperature rise because of decreased shading, and lowers concentrations of dissolved oxygen, resulting in conditions that are unsuitable for many fishes and freshwater invertebrates. Road construction, logging, and shifting agriculture, particularly in mountainous regions, result in soil erosion and thus increased sediment loads in rivers, which further reduces water quality. Hunting also represents a major threat to some aquatic species in this ecoregion, such as crocodiles and freshwater turtles. Water pollution is a constant and increasing pressure on many water systems. Part of this problem stems from increased motor traffic on the larger rivers, but chemical runoff from agriculture and the dumping of untreated waste into lakes and rivers are also major concerns. Tourism will also contribute to pollution if it is allowed to develop in an uncoordinated manner and scenic areas such as Lake Toba in northern Sumatra are particularly vulnerable to pollution.

D. Coastal and Marine Ecosystems

1. General Status

Given that up to 60% of the world's human population lives along the coast, it seems inevitable that many highly diverse and productive coastal ecosystems should be particularly threatened. Early human settlements were common along coastlines as they offered a combination of marine and land-based sources of food, navigable rivers, and access to maritime trading routes. With the advent of industrial development, coasts also offered a superficially simple solution to the growing human populations and their wastes, namely, dumping in large coastal rivers. With few areas of the globe now out of reach by modern transportation, even the most remote coastlines are now subject to tourism impacts as travelers seek ever newer opportunities to enjoy unspoiled beaches.

The impacts of human activities on marine and coastal areas fall into three main categories: (1) habitat destruction and degradation through direct activities such as reclamation, coastal constructions, dredging, and damaging fishing techniques; (2) deterioration in quality of habitat and of the water through pollution; and (3) damage to biological communities and living resources through unsustainable levels of harvesting. The World Resources Institute (1996) reported that more than one-third of the world's coastlines are under a high degree of threat from development-related activities. More than 70% of the European coastline is considered to be under a high degree of threat.

2. Major Threats to Coastal and Marine Ecosystems

Threats to coastal and marine ecosystems arise from a wide variety of human impacts and vary considerably in different parts of the world. In the temperate and industrialized regions, areas such as the Wadden Zee along the Netherlands coast show the effects of many centuries of human impact. Much of the biological richness of the Wadden Zee derives from its mudflats (wadens), which appear to be decreasing as a result of the construction of dykes and barriers that affect not only the immediate vicinity but also the flow and direction of water currents and sedimentation patterns. Pollution and eutrophication, caused by synthetic organic substances, heavy metals, oil, and a surplus of nutrients, have been identified as a major threat to the area's wildlife populations. The use of tributyl tin (TBT) as an antifouling agent in paint has resulted in a sharp decline of two species of whelk. Shorebirds are threatened by oil spillages in the Wadden Zee, and pollutants such as chlorinated hydrocarbons have caused reduced breeding success among common tern (Sterna hirundo) populations. High levels of pollutants may also interfere with the immune systems of certain species, and in 1998 a large number of harbor seals died from a viral outbreak. Many of the region's natural resources have been overexploited, and as early as the end of the nineteenth century native oysters began to disappear. Natural mussel beds have also dramatically declined, and in large parts of the Wadden Zee mechanized cockle fisheries continue to disturb the mud surface.

In comparison to the temperate regions, coastlines in much of the tropics are only beginning to be affected by industrial development. More typically, the major threats are rapidly expanding human settlements, the release of untreated sewage, and depletion of natural resources such as mangroves or fish. Coastal marine ecosystems in eastern Africa are biologically diverse, but they are also increasingly threatened by expansion of coastal populations and development. Corals form an almost continuous fringing reef along the entire coastline of eastern Africa. The western coasts of the
islands of Zanzibar, Pemba, and Mafia are characterized by patch reefs, whereas well-developed fringing reefs predominate on the eastern sides. One of the most biologically diverse areas—the Bazaruto Archipelago in Mozambique—supports a range of marine habitats, including deep-sea areas, coral reefs, rocky intertidal areas, sandy beaches, tidal sand flats, seagrass meadows, and mangrove communities. Marine turtles and many species of marine mammals are found in these coastal waters, including the highly threatened dugong (Dugong dugon). The mangroves are spawning and nursery habitats for many fish and crustacean species, and provide an invaluable ecological service by filtering riverine sediments that can damage nearby coral reefs. Environmentally harmful fishing practices, such as dynamite fishing, as well as overfishing, pollution, and uncontrolled tourism development, threaten the survival of these reefs and other coastal ecosystems throughout the region.

3. Endangered Coastal and Marine Ecosystems

a. Sand Dunes

Sand dunes are unique ecosystems occurring at the margins of the land and sea, founded upon the sands that are washed up by the movements of the sea. Sand dunes may stabilize and become forested or covered in shrubs and grasses. Alternatively the dunes may move landward, or be dispersed by subsequent tides. Over time, substantial areas, such as Fraser Island off the eastern coast of Australia, can be formed by this process. In Europe there are less than 428,000 ha of dunelands remaining on Atlantic coasts and widespread afforestation with exotic species has changed their character. The situation is more acute along the southern European coastline, where sandy beaches are the main attraction for many of the 100 million tourists who visit the Mediterranean each year. Construction of coastal towns and resorts has resulted in an estimated 71% loss in dune areas since 1900.

b. Mangroves

Under the right conditions, extensive mangrove forests can be found throughout the tropics in shallow bays and inlets and along rivers. These biologically rich communities have been subjected to enormous pressure from human settlement. By 1996, it was estimated that half of the world's mangroves had been destroyed. The main reasons for this loss in the past have been the felling of firewood or the production of charcoal. More recently, the rapidly expanding shrimp aquaculture industry represents the greatest threat to the world's remaining mangroves. The clearing of mangrove forests to make way for shrimp ponds is responsible for about half of all the mangrove loss in recent years, and has greatly reduced the extent of mangroves in Southeast Asia, South Asia, and Latin America. Thailand has lost more than half of its mangrove forests since 1960 as a result of the booming shrimp aquaculture industry. In Ecuador, estimates of mangrove loss range from 20% to nearly one-half of Ecuador's original 362,000 ha of mangrove forest. Typically, the shrimp ponds are abandoned after a few years and new areas have to be cleared.

c. Coral Reefs

Although coral reefs occupy a small fraction (less than 0.2%) of the total area of the world's oceans, they are among the most biologically diverse of all ecosystems. Formed by the accumulation of calcium carbonate deposited by certain corals and algae over thousands of years, coral reefs cover some 600,000 km² and are the largest structures formed by living creatures. The destruction of coral reefs is caused by many human activities, ranging from coastal development and destructive fishing practices to overexploitation of resources, marine pollution, and runoff from agricultural activities and deforestation. A number of reefs of particular biological interest are also under the most serious threat, including almost all the reefs of the Philippines and coral communities in coastal Indonesia, Tanzania, the Comoros, and the Lesser Antilles in the Caribbean.

An analysis of the conservation status of the world's coral reefs (Bryant et al., 1998) found that 58% were potentially threatened by human activity. Coral reefs in Southeast Asia are the most threatened, where an estimated 80% are at risk as a result of coastal development and fishing-related pressures. The study also concluded that coral reef ecosystems are very poorly conserved, with at least 40 countries lacking any marine protected areas for the conservation of coral reefs. A widespread phenomenon—coral bleaching—became evident during the extreme El Niño weather pattern of 1982-1983. Corals became stressed by high temperatures and expelled the symbiotic zooxanthellae that provide their nutrients, leading to coral death. Large areas of coral bleaching were recorded during this period, as well as in the subsequent El Niño event in the mid-1990s. There is considerable speculation that the severity of these events may be linked to global warming caused by the accumulation of carbon dioxide and other "greenhouse" gases in the atmosphere.
The Nansei Shoto Islands, a chain of 200 islands off southwestern Japan, contain some of the most extensive and biologically diverse coral reefs in the western Pacific. The relative isolation of the islands' marine and terrestrial ecosystems has produced unusual patterns of endemism. On Shiraho reef there are at least 120 species of coral, including the oldest and biggest community of blue coral (Heliofungia actiniformis) in the Northern Hemisphere and extensive colonies of the massive porous coral (Porites australiensis), Madracis coral (genus Madracis), and staghorn coral (family Acroporidae), as well as more than 300 species of fish. These coral reef ecosystems have become seriously threatened since 1972, with up to 90% lost as a result of silt runoff from construction, farming, and logging activities.

d. Island Ecosystems

In many ways islands are among the most vulnerable of ecosystems. Islands are particularly susceptible to invasion by exotic species or rapid depletion of their resources following human colonization. Some island ecosystems have evolved in long isolation from nearby landmasses and may contain many unique plant and animal species. They are also the breeding ground for many marine species, such as turtles, seals, and seabirds, that may be vulnerable to predators on the larger landmasses. In some cases, birds have become flightless as a result of the absence of predators, making them especially vulnerable should humans or exotic species arrive. It is not surprising then that most animal and plant extinctions that have occurred in historic times have been island species (WCMC, 1992). Islands that are of particular concern for both their significant biological richness and vulnerability to human impact are those of New Caledonia, Hawaii, Madagascar, and the Galápagos.

The Galápagos Islands represent one of the most outstanding examples of the evolutionary processes that influence isolated island ecosystems and their susceptibility to human impacts. Across the many individual islands can be found arid lowlands of open cactus forest, transitional subtropical forest, moist dense forest at higher elevations, and treeless upland areas covered with ferns and grasses. Habitat destruction and degradation from grazing by introduced goats, sheep, and cattle, as well as uncontrolled fires, are a major threat. Introduced pest species such as rats and cats prey on native species. Poaching of rare and threatened species is increasing, as is the overexploitation of many marine species such as sea cucumbers (Ischnopoma fuscus) and sharks. Tourism and settlement from the mainland pose additional pressures on an already stressed ecosystem.

4. Oceans

Although the boundaries between marine ecosystems do not appear as distinct as those on land, marine ecosystems may be identified as distinct and moving water masses, often with identifiable and characteristic planktonic assemblages. The sea bottom (benthic systems) can be defined on the basis of sediment type, again associated with characteristic faunal and floral groups, though in some areas other physical and chemical features such as turbidity, light, or salinity help define the ecosystem.

Long considered a virtually infinite resource, the oceans are beginning to show signs of detrimental human impact, including algal blooms, disease outbreaks, and dramatic changes in species composition. In contrast to most terrestrial ecosystems, human impacts on open-water systems and deeper benthic systems are often not specific to any particular ecosystem. Almost no marine ecosystem can be considered immune to the effects of pollutants owing to their dispersal in the marine environment or through the food web. Endangered marine ecosystems are most obvious in those parts of the world subject to extensive industrialization, such as the North Atlantic Ocean and the Baltic, Caspian, Mediterranean, and other seas adjacent to Europe. Other ocean systems that would appear to be at a high risk include the Sea of Japan, South China Sea, Caribbean Sea, and Gulf of Mexico.

Studies of European marine systems show that land-based pollution and diffuse sources of pollution are the major causes in a general deterioration in water quality, from polychlorinated biphenyls (PCBs) in the Baltic Sea, DDT and pesticides in the Caspian, Organic wastes, including sewage, by-products from industries (pulp and paper mills or tanneries), and fertilizers contained in runoff from agriculture, are common throughout European marine ecosystems. Three-quarters of the region's pollution originates from only three countries—France, Spain, and Italy—and causes the contamination of seafood and eutrophication of enclosed bays. Throughout the region, 80% of municipal sewage is discharged untreated from coastal cities, and up to 600,000 million tons of crude oil are released annually from oil-related operations and shipping. Agricultural runoff in the form of pesticides, including persistent organochlorinated compounds, contaminate the food chain, and nitrate and phosphate run-off cause eutrophication and increased episodes of algal growth, including the poisonous “red tides.” Chemical pollution,
bottom-trawling fishing practices, and the introduction of exotic species have contributed to the depletion of indigenous marine life, such as Posidonia (seagrass) meadows.

Increasingly, overfishing is being implicated as a threat to marine ecosystems, particularly in areas such as the North Sea, which are subject to intensive exploitation. Depletion of commercial fish populations may cause changes in the species composition and adversely affect populations of birds, seals, and cetaceans that feed on these species. In addition to depletion of fish stocks, some fishing techniques have a direct impact on nontarget populations. Trawling or dragging of fishing gear, for example, can have devastating local impacts on benthic ecosystems such as the rare Norwegian coral communities (Paragorgia arboresa) or the diverse communities associated with the horse mussel (Modiolus modiolus) at Strangford Loch in Scotland. In many parts of the world, other fishing techniques have also severely damaged marine ecosystems. Drift-netting is particularly notorious for the high by-catch of species such as sea turtles, cetaceans, and seals, whereas long-line fishing has been responsible for the deaths of tens of thousands of albatross and other seabirds in southern oceans. The trawling of seamounts has the potential to destroy these unique ecosystems and their numerous unusual and restricted species.

III. CONSERVATION OF ECOSYSTEMS

There is an urgent need to improve our knowledge of the distribution and conditions of the world's ecosystems. Current national and international initiatives for developing habitat classifications and evaluation methodologies need further coordination. The information that is available points to the inescapable fact that the extent and quality of remaining natural ecosystems are in decline and in certain cases this decline is accelerating. Many ecosystems are at the point of disappearing, or being irreparably modified. Table IV gives a summary of threats to major ecosystem types. It is clear that the major threats arise as the result of (1) the need to continually increase

human food production, (2) the production of waste from human settlements and industry, (3) the overexploitation of natural resources such as timber and fish, and (4) the accidental or deliberate release of exotic organisms into the environment.

The conservation of ecosystems depends largely on the management of human-induced impacts. Factors that threaten ecosystems can be seen as falling into three categories: factors that reduce the extent of an ecosystem, factors that alter the species composition of an ecosystem, and factors that disturb ecosystem processes.

The clearing of land for agriculture, as well as the draining of wetlands, often results in the almost complete removal of the original ecosystem. Trees and larger plants are felled and removed, and the remaining vegetation is often burned. Such clearing, or deforestation, may be exacerbated by the commercial exploitation of forests and other factors. Wetlands are drained by cutting channels or by damming the supply of water upstream. The dry land that is left behind may be cropped or used for housing and other developments. The almost complete loss of many ecosystems has been a feature of agricultural development in the temperate regions of the world. Evidence of widespread ecosystem disturbances can be seen from the beginnings of modern agriculture in Europe, the Middle East, and North Africa. During this period, large areas of forest were cleared and many wetlands were drained as agriculture and human settlement expanded. Similar patterns can be observed in China and South Asia. During the 1800s and early 1900s, large areas of North America and Australia also became subject to widespread agricultural development and, in the past 50 years, this expansion has spread rapidly into tropical regions. Deforestation in the humid tropics is now of major concern and many tropical forest and wetland ecosystems in central and west Africa, Latin America, and Southeast Asia are endangered. In many cases, the extent of removal is so complete that the original ecosystem must be considered completely destroyed or, at best, confined to small viable remnants. In such circumstances there are few options for conserving the remnants, and areas that have been set aside, such as nature reserves, may provide the only tenuously viable examples of the original ecosystems.

Apart from complete destruction, most of the world's remaining natural ecosystems show some effects of human intervention. Commonly, these are factors that alter the distribution or abundance of species within an ecosystem. Although species populations constantly change, disruptions to these natural cycles can have widespread effects. Certain species, for example, are referred to as "keystone" species because of their vital role in maintaining the populations of other species (e.g., they may pollinate flowers or be large predators). When such changes affect so-called "keystone" species, then larger impacts may be observed in the rest of the ecosystem. Extensive hunting, the harvesting of timber, grazing of livestock, commercial exploitation of fisheries, or other natural resources often affect populations of keystone species and thus alter natural ecosystems, sometimes to the point where they can no longer sustain their original plants and animals. The deliberate or accidental spread of exotic animals and plants also disrupts the ecosystem as these new predators or competitors flourish at the expense of the original species. The pollution of land, water, and air may affect ecosystems by introducing additional nutrients or toxic substances into food chains, causing deaths or reduced reproductive success and consequent changes in species composition. The cumulative impact of these factors can often be observed at some distance or point in time from the original impact. The modification of a river high in the mountains, for example, may eventually affect the water quantity and quality reaching a coastal marine ecosystem, changing that ecosystem and in turn affecting the viability of coastal communities. In such cases it may be possible to manage these uses sustainably, and even to restore and rehabilitate many of the attributes of the original ecosystem.

In extreme cases, the species composition of an ecosystem or its natural processes may be so disturbed from the original that they do not appear to be capable of recovery. Such disturbance may occur, for example, with the loss of nutrients, soils, or water supply. A good example of changes in ecosystems brought about by disruptions in natural processes can be seen in the case of fire. Many ecosystem types (particularly some open forest, shrubland, and grassland communities) are adapted to frequent fires and their species may exhibit a range of responses to fire that ensure their survival and continuation. On the other hand, ecosystems such as temperate and tropical rain forests may be extremely susceptible to fires and the subsequent loss of nutrients that follows heavy rains and leaching.

The effects of climate change will pose new threats to natural ecosystems, particularly those at the edge of their climatic tolerance. Species composition might change rapidly as specialized species are replaced by more generalist species able to take advantage of changing conditions. Of course change is a natural part of evolution and ecosystems should not be considered as
The maintenance, protection, and restoration of degraded ecosystems will depend to a significant extent on the capacity and willingness of people and their governments to reduce and control the impact of human development. There are few proven methods to achieve this outcome, and indeed the trend of humanity over the past millennium has been in the opposite direction—increasing populations, greater levels of per capita resource consumption, and the rapid transformation of natural ecosystems to provide the economic resources necessary for this expansion.

Legal protection and management are clearly necessary in many cases to halt the rapid loss of ecosystem types. Although the first stated goal of the U.S. Endangered Species Act is "to provide the means whereby the ecosystems upon which endangered species and threatened species depend may be conserved," it is clear that even this relatively powerful legislation has only limited ability to achieve the aim of ecosystem conservation. The situation is obviously much more difficult in many poor and developing countries. In many cases the intent of environmental law vastly exceeds the willingness or capacity of the country to effectively implement its provisions. In such cases, international agencies, organizations, and funding bodies are required to help build this capacity and to provide training and institutional strengthening. International treaties and conventions, such as the Convention on Biological Diversity, established as a result of the 1992 Earth Summit, provide an important framework and guidelines for such international cooperation.

The major pressures on ecosystems and their biodiversity arise directly and indirectly from the amount of resources being consumed by a growing human population. Many social and economic factors contribute to this impact. Overall, however, it is the demand for food, water, housing, and material goods, and the necessary economic infrastructure required to produce these goods, that places stress on natural ecosystems. Eventually the expansion of human impact on the environment will need to be modified dramatically if more than a small collection of protected ecosystems are to survive in the future. Controlling our accelerating consumption of natural resources will require fundamental changes in the pattern of human development. There are few proven methods to achieve this outcome, and indeed the trend of humanity over the past millennium has been in the opposite direction—increasing populations, greater levels of per capita resource consumption, and the rapid transformation of natural ecosystems to provide the economic resources necessary for this expansion.

GLOSSARY

alien species Species that has been moved and established outside of its native range as a result of human activities; also called exotic species, introduced species, nonindigenous species.
aquifer Geological formation that contains and allows movement of groundwater.
endangered species Species that is at substantial risk of extinction as a result of human activities.
endemic species Species that occurs only over a limited geographical range.
eutrophication Process of increasing the productivity of an ecosystem by enriching it with nutrients.
groundwater Water that occurs in saturated soils and geological formations beneath Earth's surface.

THE EARTH'S FRESHWATERS CONTAIN A BEWILDERING DIVERSITY OF INVERTEBRATE LIFE. More than 70,000 species have already been described, and tens of thousands of species remain to be discovered and described by scientists. This diversity is not spread evenly over the surface of the globe, but is concentrated in local "hot spots," usually geologically ancient lakes, streams, or groundwaters. These hot spots often contain dozens to hundreds of species of freshwater invertebrates that are found nowhere else in the world. Because freshwaters are such an important resource for people, and have been used intensively for water supply, power, irrigation, fisheries, navigation, waste disposal, and as sites for cities, environmental conditions in many of the world's freshwaters have been altered greatly from their original states. Especially where hot spots of diversity coincide with areas of intensive human development, many freshwater invertebrates have disappeared from their native habitats. Some invertebrate species have already become extinct, and thousands of others are in danger of disappearing from the earth. Careful management of
freshwaters, especially in hot spots of high biological diversity, is needed to prevent catastrophic extinctions of freshwater invertebrates in the future.

I. INTRODUCTION

A. Freshwater Invertebrates of the World

Over 70,000 species of freshwater invertebrates have been described, representing about 570 families and 16 phyla. The world's freshwater invertebrate fauna is actually much larger than this, probably 10,000–100,000 species await discovery, and new genera and families are discovered regularly. We are particularly ignorant about what lives in groundwaters, what lives outside of Europe and parts of North America, and small, soft-bodied invertebrates. Especially widespread and species-rich groups of freshwater invertebrates include insects, crustaceans, mollusks, mites, nematodes, and rotifers. Invertebrates live in nearly all kinds of freshwater habitats; lakes, rivers, brooks, ephemeral ponds, wetlands, caves, alluvial groundwaters, and even hot springs each contain a rich and characteristic invertebrate community. Among important freshwater habitats, perhaps only the deepest groundwaters usually lack invertebrates. A typical lake or stream contains a few hundred species of invertebrates representing several dozen families and 8–12 phyla. By comparison with the better-known vertebrates, freshwater invertebrates possess a wide range of biological traits. Life spans range from days to more than a century. Many invertebrates reproduce sexually, others reproduce asexually by budding or parthenogenesis, and still others change their sexuality or mode of reproduction depending on environmental conditions. Some invertebrates produce eggs or other reproductive bodies that remain viable for years to centuries. Freshwater invertebrates include herbivores, bacteriovores, fungivores, predators, and parasites, and exhibit a wide range of specialized morphologies and behaviors to aid in food gathering. Some even use symbiotic algae to photosynthesize!

B. What Is “Endangered”?

Various terms such as “endangered,” “threatened,” “imperiled,” and “at risk” have been used to describe species that are in danger of extinction through human activities. Conservation organizations and governments typically have tried to develop a graded series of carefully defined terms, running from species only remotely threatened with extinction to those on the verge of extinction. Table I shows an example of such a system. In this article, “endangered” is used loosely to mean a species or population that is at substantial risk of becoming extinct over the next few decades as a result of human activities.

C. Causes of Endangerment

The specific causes of endangerment of freshwater invertebrates are highly varied from case to case. It would be impractical (and probably not very illuminating) to discuss all the known cases of endangerment of freshwater invertebrates. Further, because information about the world's freshwater invertebrates is still so incomplete, a catalog of known cases of endangerment many be misleading. Instead, the focus here is on the problem of endangerment in a more general way, and selected case studies are used to illustrate major points.

Endangerment is a product of three factors: the preexisting vulnerability of a species, the pressure of human activities, and the sensitivity of the species to specific human activities (Fig. 1). Thus, a species may become endangered if it already was vulnerable to extinction prior to human involvement, if human activity TABLE I

II. VULNERABILITY OF FRESHWATER INVERTEBRATES

A. Small Ranges

Many species of freshwater invertebrates had small ranges even before human intervention. Species with small ranges are called narrowly endemic species. For example, half of the 281 North American pearly mussel species were found in only one to three states, even before human intervention. Such species may have had elevated probabilities of extinction through natural catastrophes, and certainly are especially vulnerable to human activities (Fig. 2). Small natural ranges often arise through a small number of understandale processes. Because these processes are focused in certain regions and on species with characteristic biological traits, narrowly endemic species often are clustered together into small regions and concentrated in certain taxonomic or ecological groups.

1. Causes of Small Ranges

A primary cause of small ranges in freshwater invertebrates is the limited dispersal abilities of these animals. All freshwater habitats are islands in a sea of terrestrial habitats, and are more or less isolated from other similar habitats. Although streams are connected into drainage networks, the streams of one drainage network are isolated from those in other drainage networks. The dispersal abilities of freshwater invertebrates, and thus the perceived isolation of freshwater habitats, vary widely.
For animals like dragonflies, whose long-lived aerial adults are strong fliers, or ectoproct bryozoans, whose tough resting stages ("statoblasts") are readily dispersed by migratory waterfowl, the separation of freshwaters probably does not present an important barrier to dispersal or gene flow. For other animals, such as fragile groundwater crustaceans that are poor swimmers, avoid the light, and lack tough dispersal stages, adjacent streams or aquifers may be nearly as remote as distant continents, and even small barriers may prevent migration and gene flow. For instance, the present-day distribution of microparasellid isopods nearly follows the pattern of marine beaches from over 20 million years ago (Fig. 3), where these species presumably arose and from which they subsequently apparently have been unable to disperse.

The isolation of freshwater habitats may produce small ranges in two ways. First, endemic species with small ranges may evolve in place following infrequent crossing of dispersal barriers, resulting in a group of more or less closely related species whose ranges are separated by barriers to dispersal. Second, a formerly widespread species may be eliminated from most of its former range, for instance by a changing climate or the arrival of a competitor, stranded in small refuges, and be unable subsequently to disperse out of the refuges. This second mechanism may become especially important for the freshwater biota if humans cause large changes in regional or global climate, especially because habitat alterations and pollution have eliminated many of the natural dispersal corridors between freshwater habitats.

Finally, a species may have a small range because it requires an unusual habitat, which is itself rare. For example, the thermosbaenacean crustacean Thermosbaena mirabilis was described from ancient Roman warm baths and is known from only a few thermal springs in Tunisia. Its small range presumably derives from its unusual habitat requirements as well as its limited dispersal abilities.

2. "Hot Spots" of High Endemism

Because of processes of speciation, extinction, and dispersal do not occur uniformly over the earth, species richness and endemism vary greatly across the world's freshwaters. Some bodies of water contain more than 1000 invertebrate species, many of them unique to that single body of water. At the other extreme, some bodies...
of water support fewer than 100 invertebrate species, all of them widely distributed. We might expect sites of high richness and endemism to be habitats of great age, habitats where dispersal is limited, either by geographic isolation or by characteristics of the habitat, or habitats that harbor animal groups that are prone to speciate. Thus, many ancient lakes (Baikal in Siberia, Tanganyika and Malawi in Africa) and river systems (the Tennessee in the United States, the Mekong in Southeast Asia) that have not been recently disturbed by glaciation, marine submergence, or desiccation support unique assemblages of invertebrates. Many aquifers seem to contain a high proportion of endemic species, probably because both the characteristics of aquifers (slow water flow, tortuous passageways within aquifers, and barriers between aquifers) and the characteristics of their inhabitants (e.g., fragile bodies, strong thigmotaxis) discourage long-range dispersal. Conversely, glacial lakes and temporary ponds rarely support locally endemic species. Although we know many hot spots of freshwater invertebrate diversity, it probably is not yet possible to produce a reliable global map that shows all major hot spots.

3. Species with High Endemism

Groups of animals vary in their tendency to form new species with small ranges. As already suggested, narrow dispersal probably allows the development of local species, whereas broad dispersal probably provides so much gene flow across populations that speciation is unlikely to occur. Other traits that have been suggested to encourage local speciation include a requirement for outcrossing (as opposed to selfing hermaphroditism or parthenogenesis), production of large young, live-bearing (as opposed to egg-laying), and narrow habitat requirements. The importance of each of these (and other) factors is unclear, but it is clear that groups of freshwater invertebrates do differ widely in their degree of endemism.

Figure 4 shows two examples. Dragonflies, most of which are strong fliers and easily cross drainage divides, are much less likely to have small ranges than pearly mussels, which do not readily cross drainage divides. Even the same group of animals may have dramatically different degrees of endemism depending on the habitat occupied. Thus, groundwater cyclopoid copepods have very much smaller ranges than their relatives in surface waters. This difference presumably arises because groundwater animals have distinctive behaviors and especially because dispersal between aquifers is more difficult than dispersal between lakes or streams.

4. Traits of Narrowly Endemic Species

Narrowly endemic species may possess traits (other than small range size) that influence their vulnerability to endangerment. For example, the limited dispersal abilities and specialized habitat requirements of many narrowly endemic species may make them particularly sensitive to and slow to recover from catastrophes, whether natural or human-caused. Further, some environments that contain endemic species may encourage the development of traits that influence species vulnerability. Thus, in the food-poor groundwater environment, many animals have sparse populations, delayed maturity, and low reproductive rates, all of which probably add to their sensitivity to human impacts.

B. Sparse Populations

Species may be vulnerable to endangerment because their populations are sparse. Because population densities of freshwater invertebrates are much less well known than their geographic ranges, relatively little is
Rivers in the Southeast United States

The U.S. Southeast (extending roughly from the Ohio River south to the coastal plain of Alabama and Georgia, plus the highlands of Arkansas, Missouri, and Oklahoma) contains ancient river systems with an extraordinarily rich biota. This region was not covered by Pleistocene glaciers, nor was it covered by the sea or desiccated for hundreds of millions of years, so river systems like the Tennessee, Cumberland, and Alabama (and their associated aquifers) are very old. The rivers and groundwaters of the Southeast are examples of biologically rich ecosystems that have suffered badly from human activities.

The freshwater invertebrate fauna of the Southeast contains hundreds of species of mollusks, crustaceans, insects, mites, and other animals (Fig. 7) that are found nowhere else in the world. Dozens of genera and two families of invertebrates [Parvidrilidae (Oligochaeta) and Neoplanorbidae (Gastropoda), the latter now probably extinct] are known only from this region. Many of these species have small ranges within the Southeast and may have occurred in only one stream. Despite a long history of scientific study in the Southeast, new species and genera of freshwater invertebrates are discovered regularly in the region.

As is the case for many river systems, the streams and rivers of the Southeast have been profoundly affected by human activities. Impoundments have been especially damaging to the invertebrate fauna. All of the large rivers in the region have been extensively impounded for flood control, hydroelectric power, and navigation, to the point that some of the large rivers have been converted into a continuous series of reservoirs. These reservoir systems differ from natural rivers in their hydrology, temperature, chemistry, sediments, and so on, and often are unsuitable for the native riverine biota. Other physical alterations of stream channels, such as channelization, dredging, diking, and instream gravel mining, also have severely damaged the freshwater biota in parts of this region. Further, as in most developed countries, these river systems have been badly polluted by toxins, nutrients, and sediments from industries, farms, and cities. Coal is mined in parts of the Southeast, which brings acid mine drainage and fine sediments into streams. Finally, invasive species, particularly the zebra mussel and biotic exchanges through the Tennessee–Tombigbee Waterway, may affect the southeastern freshwater fauna.

As a result of these massive changes to southeastern rivers, much of the freshwater invertebrate fauna is extinct or imperiled. Among the mollusks, the only group for which reasonably complete data are available, about 60 species and 4 genera from the Southeast are now extinct. Literally hundreds of additional mollusk species, representing over half of the native fauna, are threatened or endangered. Hundreds of southeastern crayfish and aquatic insects are likewise rare or endangered, and additional species of small, poorly known animals like copepods, isopods, amphipods, and oligochaetes are doubtlessly extant or at risk of extinction.

The southeastern fauna is now receiving some protection from the U.S. Endangered Species Act and parallel state laws. Nevertheless, unless the continuing damaging effects of human activities like impoundments are reversed or remediated, it is difficult to be optimistic about the long-term prospects for the southeastern freshwater biota.

Sources: Benz and Collins, 1997; Lydeard and Mayden, 1995.
Much of the arid interior of eastern Australia is underlain by a large aquifer called the Great Artesian Basin. Freshwater and brackish-water springs occur along the margins of this aquifer in Queensland, New South Wales, and South Australia. These springs range in size from small, moist seeps to large (>100 liters/sec), flowing springs, and some of them have built up large (>10 m high) hills of sand and mineral deposits, and so are locally called “mound springs.” Although perhaps connected to one another in the past, when the Australian climate was wetter, the springs are now separated from one another by a few meters to many kilometers of desert, and are not connected by streams or rivers.

Like many springs in arid regions, the springs of the Great Artesian Basin support animals that live nowhere else in the world. Many of these species are found in only one or a few neighboring springs. Only the fish and the snails of these Australian springs have received serious study. About 25 species and 3 genera of snails have so far been found to be endemic to the springs (Fig. 8). All of the endemic snails belong to the Hydrobiidae, a widespread family that has produced flocks of endemic species in springs, caves, and groundwaterers in the Balkans, the arid Southwest of the United States and Mexico, and elsewhere. Although these snails may be very abundant in the Australian springs (>1,000,000/m²), some species are restricted to one or a few springs, and all are highly vulnerable to human impacts. The endemic fauna is thought to have originated by speciation in the more or less isolated springs, perhaps after a more widespread fauna was stranded in the springs by an increasingly arid Australian climate in the Pleistocene.

The chief threat to the spring fauna is from development of wells in the Great Artesian Basin. Because this is an arid region, there is great demand for water for humans and livestock. When new wells are brought into production, the groundwater level drops, causing springs to dry up. Additional threats include the trampling of springs by livestock, which has badly degraded many springs, conversion of springs into pools by excavation or damming, and introduction of alien species (so far, the mosquitofish, Gambusia affinis, seems to be the only potentially damaging alien in the springs). Over the past two decades, the springs of the Great Artesian Basin have come to be recognized as important habitats for conservation, and steps are being taken to limit at least local impacts from grazing and habitat alterations. Nevertheless, many springs, especially in New South Wales, have dried up as a result of groundwater extraction, and many have been badly altered by livestock or people. It seems likely that at least some of the unique invertebrates of the Great Artesian Basin have gone extinct, and the remaining fauna is at risk of loss.

In arid regions around the world, extreme isolation of aquatic habitats has promoted speciation and development of endemic invertebrate faunas. As in the Great Artesian Basin, water in arid regions is a critically important resource that has been exploited heavily by people. Consequently, freshwater invertebrates of arid regions around the world are endangered by forces similar to those at work in this basin.

**Box 2**

**Mound Springs of the Great Artesian Basin in Australia**

Much of the arid interior of eastern Australia is underlain by a large aquifer called the Great Artesian Basin. Freshwater and brackish-water springs occur along the margins of this aquifer in Queensland, New South Wales, and South Australia. These springs range in size from small, moist seeps to large (>100 liters/sec), flowing springs, and some of them have built up large (>10 m high) hills of sand and mineral deposits, and so are locally called “mound springs.” Although perhaps connected to one another in the past, when the Australian climate was wetter, the springs are now separated from one another by a few meters to many kilometers of desert, and are not connected by streams or rivers. Like many springs in arid regions, the springs of the Great Artesian Basin support animals that live nowhere else in the world. Many of these species are found in only one or a few neighboring springs. Only the fish and the snails of these Australian springs have received serious study. About 25 species and 3 genera of snails have so far been found to be endemic to the springs (Fig. 8). All of the endemic snails belong to the Hydrobiidae, a widespread family that has produced flocks of endemic species in springs, caves, and groundwaterers in the Balkans, the arid Southwest of the United States and Mexico, and elsewhere. Although these snails may be very abundant in the Australian springs (>1,000,000/m²), some species are restricted to one or a few springs, and all are highly vulnerable to human impacts. The endemic fauna is thought to have originated by speciation in the more or less isolated springs, perhaps after a more widespread fauna was stranded in the springs by an increasingly arid Australian climate in the Pleistocene.

The chief threat to the spring fauna is from development of wells in the Great Artesian Basin. Because this is an arid region, there is great demand for water for humans and livestock. When new wells are brought into production, the groundwater level drops, causing springs to dry up. Additional threats include the trampling of springs by livestock, which has badly degraded many springs, conversion of springs into pools by excavation or damming, and introduction of alien species (so far, the mosquitofish, Gambusia affinis, seems to be the only potentially damaging alien in the springs). Over the past two decades, the springs of the Great Artesian Basin have come to be recognized as important habitats for conservation, and steps are being taken to limit at least local impacts from grazing and habitat alterations. Nevertheless, many springs, especially in New South Wales, have dried up as a result of groundwater extraction, and many have been badly altered by livestock or people. It seems likely that at least some of the unique invertebrates of the Great Artesian Basin have gone extinct, and the remaining fauna is at risk of loss.

In arid regions around the world, extreme isolation of aquatic habitats has promoted speciation and development of endemic invertebrate faunas. As in the Great Artesian Basin, water in arid regions is a critically important resource that has been exploited heavily by people. Consequently, freshwater invertebrates of arid regions around the world are endangered by forces similar to those at work in this basin.

**A. Habitat Destruction and Degradation**

Humans have massively altered the physical characteristics of many freshwater ecosystems, usually without consideration for consequent effects on the biota. These physical alterations probably are the chief cause of endangerment of freshwater invertebrates. Dams have been especially damaging (e.g., Fig. 5). Above the dam, running-water habitats are converted into an artificial pool that is usually unsuited to the native invertebrate species. Below the dam, the water temperature and flows of water and sediment often are so altered that downstream reaches support a highly artificial biota as well. Finally, the dam itself is a barrier that blocks normal migrations and movements of the riverine biota. Thus, even a single dam may endanger the riverine biota for hundreds of kilometers, and many river systems are now dismembered by dozens or even hundreds of dams.
shallow-water marginal habitats have been destroyed by dredging, channelization, or filling, or separated from the main channel by dikes and levees. Further, humans often simplify shoreline habitats in both lakes and streams by straightening or filling shorelines and removing trees along and in the water. Because marginal habitats often are important for the feeding and spawning of the freshwater biota, the loss or isolation of these habitats may have grave consequences for the native biota. When water is removed from a river for irrigation or held up in a reservoir for hydroelectric generation or flood control, downstream reaches may dry up or lose critically important floods. Several of the world’s major rivers (e.g., the Colorado and the Ganges) no longer flow to the sea during dry periods. Likewise, the drawdown of many of the world’s aquifers from overuse of groundwater presumably has major effects on the freshwater biota, although these effects have scarcely been studied. Finally, mining of underwater deposits (for gravel or gold, for instance) may have devastating effects at the site of mining, as well as far downstream through sediment transport and far upstream through headcutting of the streambed.

B. Pollution

Water pollution is another widespread activity that has had severe effects on freshwater invertebrates. Rivers and lakes often have been used for waste disposal. These wastes include sewage and other organic matter, the decomposition of which may reduce concentrations of dissolved oxygen to levels too low to support most species of invertebrates. Other wastes include substances (e.g., mercury used in gold mining, acid precipitation from power plants and automobiles) that are directly toxic to freshwater invertebrates. Particularly in industrialized regions, long reaches of streams and rivers have been nearly sterilized of invertebrates as a result of severe, chronic pollution (e.g., Fig. 6).

In addition to pollution caused by deliberate waste disposal, pollution may arise from a wide range of human activities in the watershed. Thus, conversion of forests or native grasslands to agricultural fields or development typically greatly increases loadings of sediments, nutrients, and toxins that are washed in from the altered watershed. These “non-point-source” pollutants are more difficult to track down and control than point loadings of pollutants from factories, yet may have equally serious effects on freshwater ecosystems. While pollution has come under partial control in many developed parts of the world, residual pollution from past releases and inadvertent spills still damage the freshwater biota. Spectacular recent examples include a large spill of pesticides into the River Rhine following a fire at a Sandoz chemical plant, which killed fish and invertebrates for hundreds of kilometers, and the overturning of a truck that spilled a rubber accelerator into the Clinch River, Virginia, which killed most aquatic animals in a 10-km reach, including hundreds of endangered mussels. This was the largest “take” of endangered species in the United States since the Endangered Species Act was passed in 1973. Of course, in many less-developed parts of the world, water pollution is still poorly controlled.
Lake Baikal, part of a rift system in southeastern Siberia, is the oldest (>25 million years old) and deepest (>1600 m deep) lake in the world, and covers 31,500 km². It is the only great rift lake that is oxygenated to its bottom, allowing colonization of the entire lake by a wide range of invertebrates. So far, more than 1400 species of invertebrates have been found in the lake, about 60% of which live nowhere else in the world. Many genera and four families of invertebrates [Labsomirskiidae (Porifera), Baicalarciidae (Turbellaria), Baicaliidae (Gastropoda), Benedictiidae (Gastropoda)] are endemic to Baikal. Probably the most remarkable group of endemic species in Baikal is the huge flock (46 genera and >250 species) of endemic gammarid amphipod crustaceans (Fig. 9). These amphipods, which constitute more than one-third of all gammarid species in the world, have diversified into a wide range of morphologies and behaviors and occupy a range of ecological niches, including planktonic and benthic herbivores, detritivores, predators, and semiparasites on sponges. New species of invertebrates are found regularly in Baikal, so it is clear that the true diversity in the lake is even higher than these figures imply. A distinctive feature of the Baikal fauna is that, though nearshore areas contain a mixture of endemic and widespread species, the open water and abyssal sediments are inhabited chiefly by Baikalian endemics.

In many ancient lakes (e.g., Victoria in Africa, Biwa in Japan, Lanao in the Philippines), pollution, habitat destruction, overfishing, and introductions of alien species have extinguished many endemic species. Baikal has been protected by its remoteness and vast size, and its fauna has so far been relatively unaffected by human activities. Nevertheless, industrial and domestic waste and siltation arising from deforestation of the catchment have polluted nearshore areas. Although lakewide water quality seems not to have suffered yet, pollution is a concern in Baikal because the long residence time of water in the lake means that contaminants entering Baikal may remain in the lake for a very long time. In addition, alien species (e.g., including several fish and the aquatic plant Elodea canadensis) have the potential to affect the nearshore fauna. Lake Baikal is a remarkable example of an ancient lake with a richly endemic invertebrate fauna that may yet be preserved through careful management.

C. Direct Harvest

Some freshwater invertebrates are harvested for human use, which may contribute to their endangerment. Freshwater mussels have been fished for their shells, pearls, and meat since prehistoric times. Especially in the nineteenth and twentieth centuries, harvest rates became so high that many populations were locally depleted in Europe and North America. For example, over 13 million kg of shells from living unionids were taken from Illinois streams and rivers in a single year during peak harvests. Another heavily harvested freshwater invertebrate is the medicinal leech Hirudo medicinalis, which was collected in large numbers in Europe when blood-letting was widely practiced in the eighteenth and nineteenth centuries. As a result of this collecting and widespread pollution and habitat destruction, this animal is now threatened. Harvests of Australian crayfish from the wild are now hundreds of tons per year and have contributed to the endangerment of some species. Other invertebrates are collected for bait or the pet trade, which may contribute to local depletion of populations. Invertebrates sometimes are protected by harvest regulations (e.g., closed seasons, size regulations, bag limits), but such regulations may be inadequately conceived and poorly enforced. Fortunately, for economic reasons, harvests usually (but not always) concentrate on common species rather than rare ones.

D. Alien Species

Humans often move species outside of their native ranges. Such introductions may be deliberate, such as the stocking of trout throughout much of the temperate world, or inadvertent, such as the widespread movement of species in ships’ ballast water. Whatever the cause, these alien species often have strong ecological impacts, and sometimes are responsible for the endangerment of freshwater invertebrates. A spectacular example is the loss of native unionid mussel populations throughout much of northeastern North America as a result of competition with the introduced zebra mussel (Dreissena polymorpha). It is projected that the zebra mussel will be the final blow that will drive several
species of unionids into global extinction. Alien species may also serve as important predators of freshwater invertebrates, as in the case of the brown trout (Salmo trutta), which when introduced to Tasmania apparently preyed on and reduced the range of the unusual and endemic anaspidacean crustacean Anaspides tasmaniae. Because the effects of alien species tend to be cumulative and difficult to reverse, this is a difficult and growing problem in invertebrate conservation.

E. Global Climate Change

Humans have changed the chemistry of the earth’s atmosphere so much that significant changes in global climate are expected in the twenty-first century. At this point, it is difficult to make precise predictions about how these changes will affect specific bodies of freshwater. In many bodies of water the changes may be varied and large, involving such diverse characteristics as temperature, hydrology, water level, rising sea level, stratification, the nature and severity of disturbances, increases in damaging ultraviolet light, water chemistry, riparian vegetation, and food quality. In regions where freshwater becomes scarcer while human demands for water continue to grow, human destruction and degradation of freshwater habitats probably will become more severe. Even though we cannot yet specify the details of global climate change, it is almost certain that this change will endanger or extinguish many freshwater invertebrate species. A rapid, large change in climate will make habitats unsuitable for some of their native species. To survive, such a species will have to disperse to a body of water with suitable ecological conditions. As we have seen, though, the dispersal rates of many freshwater invertebrates are slow, almost surely too slow to keep up with the pace of climate change that current models predict. Further, human modifications to waterways (e.g., impoundments) probably have made long-distance dispersal more difficult.

IV. NUMBER AND DISTRIBUTION OF ENDANGERED FRESHWATER INVERTEBRATES

How many of the world’s freshwater invertebrates are endangered, and where do they live? The most comprehensive list of endangered animals available is the IUCN Red List (compiled by the World Conservation Union), which includes 1151 species of freshwater invertebrates (Table II). Although an enormous amount of work by experts went into compiling the IUCN list, it is clearly incomplete. The list is dominated by large, conspicuous, and attractive animals (mollusks, decapods, dragonflies, and damselflies). There is no reason to believe that smaller and less conspicuous animals are less endangered, but there is simply insufficient information on the status and trends of their populations to identify many endangered species. Likewise, almost 80% of IUCN-listed species are from North and Central America, Australia, or Europe, which probably reflects the geographical distribution of conservation biologists as much as the actual distribution of endangered freshwater invertebrates. Another way to assess global en-

dangerment of freshwater invertebrates is to examine where damaging human activities coincide with areas of high endemism (Table III). Areas where freshwater invertebrates are especially likely to be endangered include river systems throughout much of the unglaciated world, groundwaters and springs in arid and semiarid regions, and many industrialized areas.

Except in or near areas covered by Pleistocene ice, recently emerged from the sea, or desiccated, river systems often support species that are endemic to that drainage basin. Most river systems have been very highly modified through impoundment and other physical modifications, water withdrawals, and pollution. Thus, we could project that most old river systems probably contain endemic invertebrates, and that many of these invertebrates probably are endangered as a result of human activities (see Box 1 on the U.S. Southeast, for example). Only species that are good dispersers and thus live in many drainage basins or are habitat generalists and thus occur in nonriverine environments are likely to escape endangerment. Human impacts on rivers are almost global, and even river systems that have not yet been heavily impounded and modified (e.g., some basins in Southeast Asia and central Africa) are facing impoundment and other large modifications in the coming decades.

A second area where we might expect to find many endangered invertebrates are groundwaters and springs in arid and semiarid regions (e.g., northern Africa, the American Great Plains and Southwest, and Australia).

These environments typically support highly endemic invertebrate faunas that are probably very sensitive to human impacts. Throughout much of the world, humans living in arid and semiarid regions are pumping water out of aquifers faster than it can be replenished, resulting in large, rapid drops in the water table, which in turn dries up springs and aquifers. We know that desert spring communities are endangered (see Box 2 on Australian springs), and it is possible that aridland aquifers are experiencing large but unseen losses in biodiversity.

In addition to these current threats to freshwater invertebrates, we can expect increasing problems in any regions of rapid human population growth or economic development (e.g., China and Southeast Asia) from the wide range of impacts that typically accompany human populations. Further, any rapid changes in climate probably will cause endangerment and extinction of freshwater invertebrates. These climate changes are projected to be most severe in middle to high latitudes. Because of glaciation, endemism of freshwater invertebrates is higher in midlatitudes than at high latitudes, so impacts of climate change may be most severe at midlatitudes, especially where the freshwater fauna and environments already have been damaged by human activities. Again, the poorly dispersing species will probably be most severely affected.

As to the question of how many freshwater invertebrates actually are endangered (or extinct) globally, there is no certain answer at present. Only for a few

conspicuous and well-studied invertebrates (e.g., unionoid mussels, odonates) are the IUCN estimates likely to be an accurate reflection of actual endangerments. A reasonable guess might be that 3000–10,000 of the world’s freshwater invertebrate species are extinct or endangered as a result of human activities.

V. PROTECTION OF ENDANGERED FRESHWATER INVERTEBRATES

Although freshwater invertebrates are protected by international, national, and local regulations, this protection often is inadequate, for several reasons. First, lists of protected species usually underlist invertebrates and include only the largest, most conspicuous species. For instance, in the United States, only 111 domestic species of freshwater invertebrates are protected under the Endangered Species Act (compared with 318 species of vertebrates), all but 25 of them mollusks. Thus, many species of endangered freshwater invertebrates, especially small and inconspicuous animals, are not being protected by existing regulations. Second, simply being listed as a protected species may not provide enough help to endangered invertebrates. In many countries, resources for managing endangered species are insufficient, and attention naturally goes to the larger, more charismatic species. In a recent year in the United States, half of all money spent on endangered species was directed to just seven species, all of them vertebrates. As a result, so little money and attention may be spent on invertebrates that plans for recovery of invertebrate species often are general and not pursued aggressively. Third, current approaches to species protection may be inadequate to protect species over the long term. Often, legal protection focuses on trying to prevent further losses from the remaining small populations of an endangered species, without adequate attention to removing the threats that endangered the species in the first place. Consequently, legal protection may slow the rate at which an invertebrate species approaches extinction without reversing its downward trajectory.

How might we more effectively reduce extinction rates of freshwater invertebrates? First, we need to devise ways to protect species without formally listing them. Human activities will endanger or extinguish many species of freshwater invertebrates before we ever
FIGURE 9  Endemic gammarid amphipods from Lake Baikal, showing some of the wide diversity of body forms. Body
lengths are 1.5–6 mm. [From Salemaa, H., and R. Kamaltynov. (1994). The chromosome number of endemic Amphipoda

with permission.]
gather enough information on their status to satisfy requirements for legal listing, and before we have enough information on their biology to develop effective species-specific plans to protect them. One way to do this is to take advantage of the fact that many species of endemic freshwater invertebrates co-occur in hot spots by protecting such hot spots from the most damaging of human activities (e.g., dams, excessive water withdrawals, toxic pollution). Such a program of hot spot protection will require better identification, recognition, and protection of hot spots. Nonetheless, it may require less research and provide more effective protection to the world’s freshwater invertebrates than existing species-based programs. Of course, not all endangered species occur in hot spots, so species-based research and protection will necessarily have to accompany any program of hot spot protection. Further, conservation biologists and policymakers need to be more aggressive in identifying and removing threats that endanger species rather than just trying to protect the few populations that have somehow escaped threats. This will require creative thinking about how to preserve or restore essential features of habitat without making unrealistic demands on humans.

A second class of possible solutions could be focused on alleviating the dispersal limitations that are so acute for many freshwater invertebrates by actively establishing new populations of endangered species. This class of solutions is motivated by two main concerns. First, simple protection of existing populations of endangered species may fail to assure long-term survival because natural or human-caused catastrophes (e.g., the Sandefjord spill) or normal population fluctuations ultimately may drive many isolated populations into extinction. Second, it seems likely that global climate change may occur faster than the abilities of some freshwater invertebrates to disperse into suitable habitats. To preserve species under these conditions it may be necessary to deliberately establish populations of endangered species in new locations where suitable habitat exists. Several serious problems attend this approach. First, we currently cannot reliably identify “suitable habitat” for most freshwater invertebrates. Second, we do not have good protocols for reintroductions for most species. Finally, many biologists feel that it is unethical to introduce species outside of their known historical ranges (of course, for many invertebrate species, the known historical range is much smaller than the actual and unknowable historical range).

Despite these problems, it may be necessary to confront the problem of species reestablishments, especially if climate change in the twenty-first century is substantial. Clearly, we will need much better information on how fast species are able to disperse in response to a changing climate (to identify which species, if any, will perish without intervention), practical information on how to establish populations of freshwater invertebrates, and reliable models to predict whether the species we move will have undesirable effects in their new homes.

Bibliography

Mammals constitute only about 10% of all vertebrates and less than 0.3% of all known species of organisms, yet endangered mammals (mammals facing an imminent threat of extinction) have received a disproportionate amount of attention and conservation efforts. To a large extent this is the result of the higher visibility and appeal of mammals compared to members of other taxa. This stems in part from our own relationship to this group, both evolutionarily and in the roles that other mammals play in a wide range of human activities from subsistence hunting to sport and commercial activities to domestication for food, work, and companionship.

I. MAMMALIAN DIVERSITY

Mammals can be found from the arctic to the tropics, on every continent, on many of the smaller islands, and in all of the oceans. There are wholly aquatic mammals (Cetacea), semiaquatic mammals, terrestrial mammals, arboreal mammals, fossorial mammals, and even aerial mammals (Chiroptera). Mammals fall into three main groups: the monotremes, who lay shell-covered eggs and have a number of physiological structures in common with reptiles, including a single urogenital opening; the marsupials, noted for a suite of physiological traits including an incomplete placenta, a female bifid...
reproductive tract, and usually an abdominal pouch for the almost-embryonic young, and the eutherians, who have a choriovallantoic placenta and give birth to relatively precocial young. Mammals may live for over a hundred years, as suspected in some cetaceans, or as short as one year, as in the “annual” males of the marsupial Antechinus. Mammalian social systems vary from solitary individuals through a wide range of social organizations to the termite-like sociality of the naked mole rat (Heterocephalus glaber). Mammals can have individual home ranges as small as a few square meters to systems where groups of tens of thousands migrate together (e.g., wildebeest, caribou) and migrations may cover thousands of kilometers (e.g., gray whales). Mammals have evolved to feed on virtually anything that might qualify as edible, from invertebrates, to other mammals, to fungi, grasses, leaves, bark, and even conifer needles. The variety of niches utilized by mammals and their behavioral and physiological adaptations are enormous—it is difficult to think of a niche not already occupied by a mammal, from aquatic grazer (the Sirenia) to aerial piscivore (Noctilio and two other genera of bats).

Not only can mammals be found in most places on earth, many species can have dramatic effects on their ecosystems. Classic examples include the alteration of drainage systems and vegetation patterns caused by beaver dams; the alteration of bush and forest to grassland caused by elephant foraging; the alteration of forest pattern and structure caused by sciurid seed predation, caused by elephant foraging; the alteration of forest pattern and structure caused by grazing from both large and small rodents such as the prairie dogs (Cynomys) and viscachas (Lagostomus maximus). Many of these effects have been shown to increase biodiversity of both plants and animals within the region of modification.

Despite the high visibility and appeal of mammals and their significance to ecosystems, we still know astonishingly little about most species. This is especially true of the smaller, more cryptic, and nocturnal groups, such as the rodents, insectivores, and bats, which make up the bulk of mammalian species diversity. Medellin and Soberon (1999) point out that 459 new species of mammals were described between 1983 and 1993 (partly due to laboratory genetic investigations), with over half weighing under 100 g. For many of these and other species, there is not even basic information on population size, geographic range, or even whether the species is still extant. This also holds true for larger, more conspicuous species. For example, there is almost no information regarding population numbers, specific locations, or even existence for the dhole (Cuon alpinus), a large, pack-living canid, throughout most of its putative range in Asia.

II. A BRIEF HISTORY

A. Early Mammalian History

The history of mammals has been traced back approximately 250 million years to offshoots of the therapsid reptiles in the Triassic. According to limited fossil evidence, the first major radiation of mammals occurred in the Jurassic, about 100 million years ago. Although the diversity of mammals was increasing at this time, with marsupials and placentals in evidence by the early Cretaceous, these early mammals tended to have small and fairly uniform body sizes. A number of hypotheses have been generated to explain both the increase in mammalian diversity and the small body size. The breakup and then reattachment of the continents allowed for isolation, speciation, and then faunal change, and the development of angiosperm plants also undoubtedly resulted in coevolutionary adaptations and speciation by a wide range of mammals. Small body size perhaps was influenced by the dominance of reptiles, which may have forced mammals into a secretive, nocturnal lifestyle where a small body size would be an advantage. An explosive mammalian radiation occurred in the Paleocene, again partly from repeated separations, isolation, and reintroductions as continents continued their movements, and perhaps further spurred by the loss of a wide range of large reptilian competitors during the great extinction event of 65 million years ago.

B. The Pleistocene Extinctions

Between 10,000 and 10,000 years ago a number of sudden and major die-offs occurred, almost entirely among large terrestrial mammals. Approximately 11,000 years ago in North America, a megalaulan extinction event claimed up to 33 genera of large mammals within a span of only 1000 to 2000 years, including mastodons, mammoths, ground sloths, camels, horses, and various large predators such as saber-toothed cats and dire wolves. A similar extinction event involving 46 genera of mammals occurred in South America between 13,000 and 10,000 years ago. In Australia, 13 genera of large mammals disappeared about 30,000 to 20,000 years ago. Two hypotheses have been forwarded to ex-
plain these extinction events. The first is climate change, as in the end of the Ice Age in North America. The second hypothesis relates to the arrival and subsequent hunting of large herbivores by humans, as it appears that all three extinction events occurred at approximately the same time that humans colonized and spread across these continents.

C. Recent Mammalian Extinctions

Many island mammal fauna suffered extinction events similar to those that occurred on the continents during the Pleistocene, although most island extinctions occurred in more recent times. On islands in the Mediterranean, 13 endemic genera vanished, including small goats and even dwarf elephants; most disappeared about 4000 years ago. A dwarf form of the mammoth disappeared from Wrangell Island at about the same time. In Madagascar, eight genera of lemurs, two genera of pygmy hippos, and what is now considered a distinct order, the Bibymalagasia (comprising two species that are variously aligned with the aardvarks and the ungulates), became extinct about 1000 years ago. In each of these cases human activity, either hunting, habitat alteration, or a combination, is thought to be the main cause. Island extinction events have continued into modern times. In the Caribbean Islands, 5 insectivores, 12 rodents, a raccoon, and a seal have all become extinct since 1600—almost a quarter of all recorded mammal extinctions during that period (Fig. 1).

Although the total number of mammalian extinctions in recent times does not appear to be large, the current rate of extinction, about 0.1% per year, is anywhere from 100 to 1000 times greater than what would be predicted from the fossil record. This rate will very likely increase in the near future. The status of 4355 species of mammals was reviewed in the 1996 IUCN Red List of Threatened Animals. Of those reviewed, approximately 40% were considered at risk, from critically endangered to near threatened. This percentage is undoubtedly a low estimate, for as mentioned the status of many mammal species is still unknown.

III. CAUSES AND THREATS

Many of the dangers that threaten other taxa also threaten mammals. These dangers include habitat loss, exploitation, disease, and exotic introductions, but there are some differences in the manner and level of these threats for mammals as compared to other taxa. For example, human persecution and harvesting pressure is probably greater for mammals than for most other taxa, with the probable exception of fish. True mammalian specialists are rare compared to taxa such as insects, where many species are entirely dependent on only one species of plant and thus are vulnerable to habitat changes that alter community structure. However, many mammals are relatively large, and their habitat needs in terms of area are greater than for most other taxa, putting them at high risk from habitat loss and fragmentation.

A number of historical mammalian extinctions have occurred due to human exploitation or introductions rather than habitat loss. Of 18 mammal species that have become extinct since 1600 and whose cause of extinction is known, eight became extinct due to direct human persecution, eight became extinct as the result of introduced predators and competitors, and only two became extinct because of habitat destruction. However, it is apparent that many mammalian species are now under a growing threat from habitat changes. The World Conservation Monitoring Centre (1992) estimated that habitat modification or loss is the major danger for more than three-quarters of all threatened mammals, and this number is likely to grow as the human population continues to increase and expand.

A. Mammalian Physiology and its Relationship to Threats

Mammals constitute a class of organisms that span an enormous size range of approximately eight orders of magnitude, from 2 g in some bats and shrews to 190,000 kg in the blue whale. However, the majority of mammals tend toward large sizes compared to other taxa, and they tend to have a correspondingly long maturation and slow reproductive rate. This puts them at risk from exploitation and other threats, as breeding rates may not be able to keep up with losses in a population. An extreme example is the blue whale (Balaenoptera musculus), whose population was lowered to 1% of its original numbers in less than a century and has not yet shown any appreciable increase, despite complete protection for more than 30 years. Large body size often means large habitat needs, which also puts mammals at risk. Estimates for self-sustaining populations of carnivores such as brown bears (Ursus arctos) and African wild dogs (Lycaon pictus) range from 1000 to more than 10,000 km² of suitable habitat, which means that many protected areas are too small to sustain long-term populations of these species.
B. Habitat Loss, Degradation, and Encroachment

Habitat loss and fragmentation is the single greatest threat to biodiversity worldwide, and this certainly holds true for mammals today. Conversion of habitats by humans into other land uses can fragment and separate mammal populations and increase the likelihood of local population extinctions and eventual species extinction. Rapid deforestation of tropical areas is a growing threat to a number of mammalian species, including many large, wide-ranging, or specialist species of primates, cats, and forest ungulates, as well as numerous small species with restricted ranges such as rodents, insectivores, and marsupials. Most of these species cannot adapt to a highly fragmented or altered landscape, and the few that do adapt often come into conflict with humans by feeding on crops or livestock.

The example of the giant panda (Ailuropoda melanoleuca) shows some of the complexities related to fragmentation and habitat loss. Pandas feed primarily on bamboo that may live for decades but then tends to flower, seed, and die en masse within certain areas. When this happens pandas must switch to other bamboo species, often having to move to new locations to find these alternative food sources. The increase in human population within the panda’s range in China has limited most populations of pandas to very small islands of habitat. A recent seeding and die-off of three species of bamboo resulted in the starvation of over 10% of the world’s remaining wild panda population.

Widely separated and very small populations of pandas may not be viable over the long term, even without the problems faced from the fluctuations in their food source. Because mammals are often relatively poor dispersers, the creation of corridors linking habitats has been suggested as a way to help some species, especially large or wide-ranging (including nomadic or migratory) ones. But for many mammals the necessary size and structure of corridors is unknown, and few management plans have yet to put this idea into practice.

C. Genetic Loss

It is generally assumed that a population’s long-term survival is at least partly dependent on sufficient genetic variation for individual fitness and population adaptability. Loss of genetic diversity and reduced fitness from inbreeding depression and the chance fixation of detrimental alleles has been presumed to reduce adaptive potential and increase the probability of extinction.
However, this has been notoriously difficult to quantify and has not yet been proven to have directly caused a decline in a mammal’s population in the wild. Other events, such as disease or predation, often complicate analysis, especially as lowered fitness may increase an individual’s susceptibility to these factors. There are some examples for which reduced genetic fitness may well be a cause for declines in mammal populations. The genetic bottleneck that occurred in cheetahs (*Acinonyx jubatus*) in the Pliocene has led to extremely low genetic variability among populations in sub-Saharan Africa and is believed to be the cause of sperm aberrations and low sperm counts. Isolation and reduction in numbers leading to inbreeding of Florida panthers (*Puma concolor coryi*) is considered to be the cause of low sperm counts, malformed spermatozoa, and cryptorchidism (undescended testicles) as well as an increase in heart defects within this population.

Another potential genetic threat to endangered mammals is hybridization. Documented cases of hybridizations involving endangered species include red wolves (*Canis rufus*) with coyotes (*C. latrans*), Ethiopian wolves (*C. simensis*) with domestic dogs (*C. familiaris*), and Asian wild ass (*Equus hemionus*) with domestic horses (*E. caballus*). Hybridization with domesticated forms or relatives is also seen as a threat to wild yaks (*Bos grunniens*), Batractan camels (*Camelus bactrianus*), Mongolian wild horses (*Equus ferus przewalskii*), Bactrian camels (*Camelus bactrianus*), and European wild can (*Felis silvestris*), among others.

Another genetic issue is the loss of native species and their replacement by common generalist species characteristic of human landscapes. This can result in a local numerical increase in species diversity but a worldwide loss of genetic diversity.

### D. Livestock and Disease

Domestic livestock and their attendant parasites and diseases have had dramatic effects on some wild mammal populations. Land clearing and overgrazing from domestic cattle, sheep, and goats have altered and fragmented landscapes, increased desertification, and reduced forage for other herbivores. The African rinderpest epizootics of the late 1800s, introduced by cattle, devastated a wide range of wild ungulate populations across the continent. More recently, African horse sickness decimated Indian wild asses, canine distemper killed one-quarter of the lions (*Panthera leo*) in the Serengeti National Park, and all eight packs of wild dogs (*Lycaon pictus*) involved in a study in the Serengeti region disappeared in 1991 with rabies as the suspected or confirmed cause. Disease can spread in the opposite direction, with equally problematic results for wildlife; for example, bison have been shot when they wandered outside of protected areas in Yellowstone National Park in an attempt to control the spread of brucellosis to cattle.

Another factor related to livestock and disease has been the erection of fences to separate wildlife and domestic animals. The results have sometimes been dramatic, such as the case in Botswana, where enormous fences were built in an attempt to control the transmission of disease. These fences blocked the natural migration routes of wild ungulates during the dry season and resulted in the deaths of tens of thousands of red hartebeest (*Alcelaphus buselaphus caama*), blue wildebeest (*Connochaetes taurinus*), and other antelope.

### E. Exploitation

Exploitation of mammals has occurred for many different reasons. Subsistence hunting is a growing pressure due to the explosion of the human population, especially in developing countries where much of the populations’ dietary protein may come from wildlife. Along with the increase in the human population has come an increase in the number of accurate firearms, including automatic weapons, that are now available to subsistence hunters. Subsistence hunting especially threatens ungulates, such as various deer and tapir species in Asia and South America—a third of all deer species and all four tapir species are now considered threatened or near threatened. Subsistence hunting also threatens aquatic mammals whose ranges have already been limited from other causes or who, like stellars and river dolphins, can primarily be found in coastal or riverine areas. Steller’s sea cow (*Hydrodamalis gigas*), the largest and only cold-water sirenian, was hunted to extinction by hungry sailors and other visitors to the north Pacific within 27 years of the first scientific description of this monotypic genus.

Commercial meat hunting has also threatened some species of mammals. The saiga antelope (*Saiga tatarica*), a migratory species of the central Asian steppes that once numbered in the millions, was hunted almost to extinction for its meat, hides, and horns, with the population dropping to a low of about 1000 individuals in the early part of the 1900s.

Until recently the fur trade was an important part of many countries’ economies and cultures. In North America this trade led to the depletion of many fur-bearing species by the early to middle 1800s, including beaver, marten, fisher, otter, and a number of species of seals. Fur hunting for sea otter (*Enhydra lutris*)
caused the population of this species to drop from an estimated 300,000 to under 2,000 by 1911, and hunting for skins was the main cause of depletion in numbers for the now-extinct Caribbean monk seal (Monachus tropicalis). More recently the market for fur resulted in heavy losses for most wild cat species, including large cats such as tigers and jaguars and the smaller spotted cats of South America and Asia. However, it should be noted that other mammal species, especially wide-ranging, abundant, and fast-breeding species such as the muskrat, raccoon, and coyote, have maintained their numbers despite heavy trapping efforts that continue to this day.

A second result of the fur trade was the introduction of fur-bearing animals outside of their ranges, with often unintended results. The accidental release of American mink (Mustela vison) into Europe now threatens the European mink (M. lutreola), as the American species breeds earlier and appears to be outcompeting its European counterpart.

Commercial hunting is not limited to fur. The hunting of whales for oil as well as baleen led to severe depletions of populations of many species in both hemispheres, with some populations driven to extinction and others lowered to below 5% of their original estimated numbers. Although bans have been in place for most species of whales for some time, many populations have yet to show signs of recovery.

Exploitation for body parts used in traditional medicine has also led to the decline in a number of mammal species. Almost every part of a tiger (Panthera tigris) is used for medicinal purposes, including the feet, fat, bones, blood, testes, penis, bile, whiskers, claws, and tail. The Asiatic black bear (Ursus thibetanus) is under great pressure from poaching for its gallbladder, which is used in traditional remedies, and the poaching of rhinos for their horns, which are used both for knife handles and traditional medicines, is the major cause of their precipitous decline. Although habitat loss, trophy hunting, and persecution played an important role in the initial decrease in tigers, bears, and rhinos, poaching for the medicinal market is now the greatest threat to their continued survival.

F. Persecution

Persecution usually takes the form of purposeful attempts to control or extirpate a species. Examples include persecution of potential livestock predators such as wolves and tigers, potential livestock disease threats such as antelope species in Africa and bison in Yellowstone National Park, potential livestock competitors such as prairie dogs in the United States, and, in the case of the American bison in the 1800s, an effort to control and eradicate the indigenous human culture that once depended on this large ungulate. In some cases, control efforts have driven nontarget species to endangered status, such as poison control efforts aimed at coyotes that eradicated the swift fox (Vulpes velox) throughout much of its range, and the prairie dog eradication efforts that eliminated the rodents over 98% of their range and drove the black-footed ferret, a predator specialist on prairie dogs, to the edge of extinction.

G. Interference

Interference can occur in a number of ways. As mentioned, fences have interfered with migratory ungulates in Africa and elsewhere. Dams have negatively affected Ganges and Indus river dolphins (Platanista gangetica and P. minor) by fragmenting populations, increasing siltation, and reducing fish prey. For the critically endangered North Atlantic right whale (Eubalaena glacialis) injuries from boat collisions and entanglement in fishing and lobster gear have accounted for as much as a third of all mortalities in a year, while for manatees in Florida boat collisions have accounted for up to a quarter of all mortality in a year. Death from net entanglement is thought to exceed reproductive rate in Hector’s dolphins (Cephalorhynchus hectori), a small coastal species from New Zealand. Spinner dolphin (Stenella longirostris) populations were significantly reduced due to drowning by tuna seiners who targeted the species because of their association with tuna schools. All three species of spinner are now listed as conservation dependent by IUCN. In Florida, the greatest cause of mortality for the endangered subspecies of key deer (Odocoileus virginianus clavium) and Florida panther is from being struck by cars. Even tourism may pose a threat. For example, tourist vehicle chases in desert environments have led to death from exhaustion for threatened African wild asses (Equus asinus) and addax (Addax nasomaculatus) in northern Africa. The expansion of the whale watching industry has led to concerns that the increasing number of boats, motor noise, and chases may negatively effect whale behavior, including disturbing migratory patterns, breeding efforts, and even separating mothers and young.

War is an extreme example of interference, and it can have an equally dramatic effect on already-rare mammal populations. Although there are arguments that historical tribal warfare may have created source buffer zones for large mammal populations (Martin and Szuter, 1999), today’s warfare results in numerous negative
effects including habitat destruction from deforestation and fighting efforts and the increase in killing of wildlife due to improved hunting efficiency from the availability of modern firearms. This combination is thought to have had an effect on most wild mammals in Vietnam, including the threatened Douc langur (Pygathrix nemaeus). Soldiers and guards may also negatively affect wildlife. For example, the disappearance of most of the remaining population of Marco Polo sheep (Ovis ammon polii) along the China-Pakistan border is attributed to target practice and trophy hunting from armed border forces. War may also cause local increases in subsistence hunting and habitat destruction from desperate indigenous and displaced people, especially in and around formerly protected areas. This appears to be the case in Ethiopia and Somalia, where rare antelope and wild ass are heavily hunted, and in western Africa, where mountain gorillas (Gorilla gorilla beringei) are under mounting pressure from human refugees seeking an escape from fighting as well as food and firewood in protected forests.

**H. Pollution**

Most documented cases of pollution affecting wildlife relate to taxa other than mammals, such as DDT and peregrine falcons or acidification and brook trout. There are cases where pollution has had an effect on populations of threatened or endangered mammals. For example, bats in southwestern North America suffered from DDT spraying, and a number of European bats have been affected by wood preservatives used in buildings and manatees (Trichechus inunguis) have been shown to exist in harbor seals (Phoca vitulina) from the Baltic. Pollution is thought to have led to infections from a calcivirus in California sea lions (Zalophus californianus) that caused abortion and premature parturition. Dall porpoises (Phocoenoides dallii) have been found to have an inverse correlation between serum testosterone level and DDE concentrations in their blubber. Pollution may also have more indirect effects, such as increased mortality of fish prey for river dolphins in the Ganges and Indus.

**I. Introductions**

Introductions of exotics, both purposeful and accidental, have had very strong impacts on some native species of mammals. These impacts may involve predation, competition, and the concurrent introduction of diseases or parasites. Most documented introduction problems have involved mammals as the pest species and have taken place on islands. Cases include the introduction of goats, sheep, and other herbivores to islands where endemic animals lack defenses against herbivory, and the introduction of omnivores such as rats, pigs, and macaques or carnivores such as mongooses and stoats to islands where endemic animals lack defenses against predators. The introduction of rabbits (Oryctolagus cuniculus) to Laysan appears to have driven three species of birds to extinction from grazing that destroyed avian food sources, both plants and insects dependent on the plants. The results from the explosive population growth of rabbits introduced into Australia is well documented, although predation by nonnative red foxes probably has had a greater negative effect on indigenous marsupials. Both pet and feral cats and dogs also pose a threat to wildlife. Feral cats in Australia are estimated to kill more than 400 million native mammals, birds, and reptiles each year, while in Argentina predation by dogs is the biggest threat to the endangered pink fairy armadillo (Chlamyphorus truncatus). Introduced aoudad (Ammotragus lervia) and feral burros in the southwest United States are considered to be potential competitors and disease vectors for the desert bighorn sheep (Ovis canadensis nelsoni). Introduced deer species have had major effects on vegetation in New Zealand, and in South America they may be serious competitors of the endangered Andean huemel (Hippocamelus brasiliensis).

**J. Multiple Threats**

For many species, a series or combination of the factors listed have led to precipitous population declines and endangerment. For the tiger, trophy hunting, eradic-
tion programs, market exploitation for fur and traditional medicines, and loss of habitat all played a role in the extinction of three races and a decline from perhaps over 100,000 tigers worldwide in 1920 to as few as 3000 today.

Even for mammals that have recovered from previous threats, new factors may arise to threaten the species. The saiga antelope recovered from commercial hunting once a ban and then regulations were put in place, rebounding from a low of only a thousand to more than 2 million in just 30 years. However, overgrazing, desertification, migratory barriers, and poaching for medicinal products now threaten the species, and the population has dropped to around 1 million animals in four widely separated regions.

IV. Locations for Endangered Mammals

A. Geographic Analysis of Endangered Mammals

As with most other taxa, mammalian species diversity tends to increase with decreasing latitude. The top eleven countries for mammal diversity are Mexico (450), Indonesia (436), United States (428), Zaire (415), Brazil and China (394), Colombia and Kenya (359), Peru (344), Tanzania (322), and India (316). Only the United States is not found entirely or primarily within the tropical zone. The number of threatened mammals is shown in Table I, with Indonesia leading the list with 128 and China and India tied for second with 75 each. Most of the listed countries also have some of the highest human densities in the world. However, some of these countries, such as Australia, have high numbers of threatened species yet relatively low human densities. In most of these cases a second factor, endemism, can explain much of the data.

B. Endemism: The Case of Australian and Island Mammals

Oceanic islands tend to have depauperate mammalian faunas, primarily because terrestrial mammals make poor oceanic dispersers. Many islands also do not have enough habitat to maintain viable populations of terrestrial mammal species. However, on islands that terrestrial mammals were able to colonize and that were large enough to sustain populations, isolation often led to speciation. Some examples of island endemism are truly spectacular, and often these locations also contain some of the most threatened species in the world. Indonesia, an archipelago consisting of more than 13,000 islands, has the second-greatest species richness in the world and also has the greatest number of endemic mammal species with 201. Indonesia also has the greatest number of threatened mammals with 128 (29% of its mammalian fauna). In Australia, out of a total of 252 species of mammals, 198 species are considered endemic. Twenty species are recorded as extinct since 1600 and, of the remaining species, 58 (23%) are considered threatened with extinction. Madagascar is the fourth largest island in the world and has been separated from mainland Africa since the Cretaceous. Because of its long isolation, all but one of the terrestrial species are endemic forms (the exception is a pig that may have been introduced). There are five families and 13 genera of living endemic primates (the lemurs), an endemic family of insectivores (the Tenrecidae), three endemic subfamilies of the carnivore family Viverridae, at least eight endemic genera of rodents, and a family of bats (the Myzopodidae). Of the endemic species, 46 (49%) are currently threatened, many from the recent loss of 90% of the island’s original forest cover. Papua New Guinea has 214 species of mammals, of which 57 are endemic; 57 species are also considered threatened. In Cuba almost half (15 out of 31) of the mammal species are endemic, and 9 of these are considered threatened. As mentioned, many of these islands have already suffered extinction spasms: of a total of 88 mammal species recorded as extinct since 1600, 53 are from islands, with 20 more extinctions occurring in Australia.

V. Which Mammal Taxa Are Most Threatened?

A. IUCN Red Data Book

Lists such as the Red Data Books are useful in drawing attention to the plight of certain species and in developing conservation and management efforts, including the creation of protected areas. The 1996 IUCN Red List of Threatened Animals attempted to assess the conservation status of every mammal species in the world. Each species was placed within one of eight categories. The first three are categories of threat: critically endangered, endangered, and vulnerable. The next three are lower risk categories: conservation dependent, near threatened, and least concern. The last two categories are data deficient and not evaluated. As well as these categories, two more exist: extinct and extinct in the

ENDANGERED MAMMALS

An analysis of endangered mammals by taxa, using the IUCN Red List of Threatened Animals (1996) shows that among the larger orders of mammals primates are the most endangered, with 41% of the species under threat (critically endangered, endangered, or vulnerable). All primate species are either on Appendix I or II of the Convention on International Trade in Endangered Species of Wild Fauna and Flora (CITES). Primate threats are many and varied, but the principal threat is habitat destruction. Because most primates have arboreal habits, tropical forest loss and fragmentation have had strong negative effects. Captures for the pet trade,
zoos, and medical research had a major impact on a number of species until recent legislation limited wild captures. Other species have been affected by subsistence hunting or accidental take from snares set for other species.

Insectivores are the next most threatened order, with almost 41% of species under threat. Many of these species are poor dispersers found in one or a few populations that are especially vulnerable to habitat alteration and fragmentation. Artiodactyls, or even-toed hoofed mammals, have 31% of the species under threat. Roughly 28% of all marsupial species are threatened, with 33% of species from neotropical marsupial orders and 26% from Australasian orders threatened. Approximately 25% of Chiroptera are threatened. Although much attention has been given to threatened members of the order Carnivora, “only” about one-quarter (24%) of the species are threatened. Rodents have about 16% of species listed as threatened, but because of the relatively large number of rodent species, this order has the highest number of species under threat with a total of 330. Among smaller orders, almost 58% of Perissodactyls (odd-toed hoofed mammals, such as horses, tapirs and rhinos) are threatened, with 4 of the 18 species critically endangered. Almost half (7 out of 15) of the species of Macroscelidea (elephant shrews) are considered threatened. Four out of five Sirenia (manatees and dugongs) are listed as vulnerable, whereas both Proboscidea (elephants) are listed as endangered.

VI. CONSERVATION

A. Conservation Legislation

An enormous number of treaties and laws govern protection for wildlife or their habitat. These measures include prohibitions or controls on taking, collection, possession, and trade of specific species, control of exotic species, and the protection of habitat, either directly through the creation of protected areas or through indirect measures such as tax incentives, permits, and zoning.

Three levels of conservation legislation exist. The first is worldwide treaties, usually involving conservation of habitat as in RAMSAR’s wetland protection, pollution issues, commercial exploitation and trade, or combinations of these issues, as in the Convention on
Biological Diversity of 1992. The second is regional treaties, such as the ASEAN Agreement covering South- east Asia or the Berne Convention for Europe. The last involves individual species or species groups, such as the creation of the International Whaling Commission or the 1973 Agreement on the Conservation of Polar Bears.

CITES (Convention on International Trade in Endangered Species of Wild Fauna and Flora), is an example of a worldwide treaty that is especially important for conservation of endangered mammals. CITES was established in 1973 to deal with the enormous level of international trade in wildlife, with estimated earnings as high as US$20 billion. CITES has three appendices, with Appendix I listing species threatened with extinction, Appendix II listing species that may become threatened with extinction unless trade is regulated, and Appendix III listing species protected under national law. Unfortunately, a treaty is only as good as the on-ground enforcement of its provisions, and while CITES has gone a long way toward stemming the tide of illegal trade in wildlife, black markets commercial exploitation continues to threaten many species throughout the world.

B. Species Survival Commissions

The International Union for the Conservation of Nature and Natural Resources (IUCN) is an international union of states, agencies, and organizations dedicated to the conservation of biodiversity, primarily through monitoring and advisory roles. IUCN now has more than 100 specialist groups within the Species Survival Commission (SSC), each focused on a particular taxa. More than 30 of the specialist groups work on mammals, ranging from entire orders such as the Rodent Specialist Group to individual species such as the Asian Elephant Specialist Group. SSC specialist groups consist of volunteer scientists and other experts who provide information on their taxa and even lobby governments for conservation and research efforts. One method of providing this information is through Status Surveys and Conservation Action Plans that describe trends, threats, and conservation options, which most specialist groups have now published for their particular taxa.

C. Protected Areas and Preserve Sizes

With human population increasing and unmodified habitat rapidly dwindling, habitat protection and maintenance is certainly the single most important conservation method for the preservation of biodiversity, including mammals. Large mammals often live at low densities and over large individual areas. A few protected meadows with the appropriate plant species may be enough habitat to maintain a population of butterflies, but an enormous tract of wilderness is necessary to sustain a viable population of rhinos or rhinos. Sadly, many large mammals, such as rhinos and tigers, are now entirely or mostly found within park boundaries, and it is uncertain whether populations are large enough to maintain themselves in the face of stochastic events and anthropogenic changes. Mammals within protected areas often come into conflict with people sharing the land or living on the edges of the preserves, and poaching may continue to cause declines in mammal populations within protected areas for a variety of social or economic reasons. A new focus on off-reserve or nonprotected area conservation of threatened mammals faces daunting challenges from multiple use, social, cultural, and economic growth issues. However, off-reserve conservation may be the only hope for some mammals, as the money and political will to continue creating protected areas is limited.

D. Captive Breeding and Reintroduction

Captive breeding has become a well-accepted way of managing and increasing populations of critically endangered species. New techniques have led to breakthroughs in captive breeding with some species, including the use of extra-specific surrogate mothers and embryo manipulation, including transfer, cryo-preservation, and microsurgical division. However, captive breeding has not worked in every case. For example, the critically endangered Sumatran rhino (Dicerorhinus sumatrensis) has not been bred in captivity despite a number of attempts, and a third of the 27 captive animals have died.

A number of captive breeding programs have led to reintroduction efforts for mammals that were extinct in the wild, including wisent (Bison bonasus) in Europe, Arabian oryx (Oryx leucoryx) in Oman, and Per David's deer (Elaphurus davidianus) in China. Other reintroduction programs have attempted to supplement decreasing wild populations; for example, 23% of wild golden lion tamarins (Leontopithecus rosalia) are now from captive-bred stock. Perhaps the best-known case of captive breeding and reintroduction of a mammal involves the black-footed ferret (Mustela nigripes). This small carnivore was once common across the North American plains, where it specialized in hunting large, colonial ground squirrels called prairie dogs (Cynomys). Prairie dogs were considered to be pests and competitors with
cattle, so an intensive eradication program eventually reduced historic prairie dog range by over 95%. The black-footed ferret subsequently declined and was thought to be extinct in the wild in the 1970s, although a small number of ferrets still existed in captivity. This captive colony suffered from physical problems, perhaps related to inbreeding as well as disease, and the colony died out in 1979, leading to fears that the species had truly gone extinct. However, in 1981 a new colony of ferrets was discovered in Wyoming. The first six ferrets to be captured for breeding died of canine distemper. The remaining wild ferrets were captured and successful captive breeding resulted in their numbers reaching about 300, with some released back to the wild. However, the program has not been without criticism: politically motivated decisions and arguments between state, federal, and private organizations have caused numerous problems and may have even jeopardized the success of the project at times. Finding suitable prairie dog colonies (both in terms of finding colonies of adequate size and the political difficulty of maintaining large numbers of what many consider to be a "pest" species) for continued reintroduction is yet another roadblock to ferret recovery.

Another successful and controversial example has been the reintroduction of gray wolves (Canis lupus) into the Rocky Mountain region of the United States, beginning in 1995 and including most recently Yellowstone National Park. The wolf population in Yellowstone, numbering more than 100, has already had an obvious effect on the ecosystem of the area, causing a decrease in some species (i.e., coyotes, through competition and killing) and an increase in other species (due at least in part to an increase in carrion from wolf kills). Wolves also appear to be altering the behavior of their ungulate prey, which in turn is having other effects on the system. This introduction has not been without controversy, partly stemming from wolf predation on livestock. During a 3-year period wolves in the Rockies killed more than 250 sheep and cattle, but a compensation fund for livestock lost to wolves has helped mitigate some of the antiwolf feelings from ranchers. Despite these problems, the success of the program has led to discussions regarding possible reintroduction of wolves into the northeastern United States.

Other predator reintroduction attempts have not fared so well, however. Recent efforts to reintroduce the Mexican subspecies of the wolf to the southwestern United States resulted in the shooting death of 5 of the first 11 released wolves. Attempts to reintroduce lynx (Lynx lynx) into parts of the Swiss Alps and the Adirondacks of New York have failed. Another lynx reintroduction at the southern limit of the species’ range in the Colorado Rocky Mountains has also had problems, with 4 of the first 13 animals starving to death. The success of many reintroductions has also been threatened by legal challenges from individuals or organizations opposed to land use restrictions or worried about potential direct conflicts with humans or livestock. Reintroductions do not always involve captive breeding. A number of African antelope and Eurasian caprines have been successfully translocated from still-viable populations into areas where they had been eradicated. One issue regarding this technique is whether there was a distinct local genotype. This is a serious problem if translocations are being considered as a method to bolster an existing but declining or no-longer-viable population, in which case mixing genotypes may result in the swamping of possible adaptive differences. There have also been introductions into areas that were not part of the original range of a species, with occasional unintended results of competition with indigenous species and habitat destruction. In one example, 11 Baha- mian hutias (Geocapromys ingrahami), an endangered rodent, were introduced to a nearby island in a successful attempt to establish a second population of the species. However, it appeared that the hutia had not lived on this second island at least within historic time, and after 16 years the population had expanded to the point where seven plant species had vanished from the island overgrazing.

Reintroductions are a complex undertaking, involving a solid understanding of the biology of the species, from feeding and breeding to individual and population genetics. The animals must be trained to survive in the wild, from finding food to socializing and, in the case of arboreal primates, even learning to move through the trees properly. The location for reintroduction should be part of the original range, be large enough to sustain a viable population, contain the correct habitat specifications, and no longer have whatever pressures resulted in the original loss of the species in the wild. Introduced animals must be closely monitored, and there must strong political and local support and extended funding for the project. Thus captive breeding and reintroduction may only be appropriate in specific cases where this kind of information and support is available.

E. Economic Incentives

Because reserves only cover approximately 5% of the earth’s surface, and captive breeding and reintrodu-
tions are only feasible for certain well-studied and well-funded species, other methods will be necessary to ensure the survival of a number of mammal species. One method is economic utilization, which applies the fact that mammals have always been heavily exploited. It also has the important potential advantage of paying for itself. Because much of the present extinction crisis of mammals has an economic incentive, this idea has won wide if cautious acceptance, although controversy still exists on issues such as lack of data on population numbers and dynamics, whether overuse is inevitable, and concerns over animal welfare.

Sports and trophy hunting has been linked with historic declines in a number of mammal species, often in conjunction with other factors such as habitat loss. However, today sports and trophy hunting is being considered as a management tool. For some species, especially big game animals, it is suggested that conservation can “pay for itself” when fees from hunters are redirected back into management. This can be most effective for polygynous species where males are not a limiting resource and are also considered desirable as trophies. Licensing and management for white-tailed deer in North America has resulted in a population explosion of that species to the point where it is now necessary to actively control deer as pests in many locations. Trophy hunting fees may also be directed back to local communities to help replace losses from subsistence hunting or nuisance animals and encourage conservation awareness and behavior. Wild goat trophy hunting programs in the mountains of northern Pakistan have resulted in locally effective conservation efforts on behalf of populations of ibex (Capra ibex) and markhor (Capra falconeri), although the long-term success of these projects is still in doubt. In Zimbabwe, the Communal Areas Management Programme for Indigenous Resources (CAMPFIRE) has had success with trophy hunting as an economic incentive for local people to manage their wildlife in a sustainable manner. However, sports hunting as a management tool is only possible when populations of the target species are large enough to support regular culling, monitoring of the target species is constant, regulations are capable of being altered if necessary, and where the political situation enables funds generated from hunting fees to be returned either directly or through other forms of management to local people to encourage their support. From the biological side, potential problems associated with the removal of dominant males include skewed sex and age ratios, lowered genetic variability, altered behavior of other group members and even the destruction of group cohesion in some targeted species, such as big-horn sheep (Ovis canadensis) and elephants (Loxodonta africana). Tourism is another method of raising funds so that the organism under protection pays for itself. This has worked well for a few charismatic species, such as mountain gorillas, but the vast majority of threatened mammal species are not capable of generating a level of public interest that will result in tourism revenues. However, it has been argued that certain charismatic species may act as “umbrellas” to create protection that will cover other species.

F. Umbrella Species: The Case for and against Charismatic Megafauna

The umbrella principle of conservation involves the protection of a large or wide-ranging species in the hopes that this will result in the protection of a number of other, smaller species. This concept has numerous advantages: it is easier to mobilize public interest toward large and charismatic species, it is easier to get funding for conservation work, and efforts to conserve large species are likely to result in conservation of large numbers of smaller species, due to the large habitat needs of the large species overlapping or including those of smaller ones. The tiger is often used as an example of a species where conservation success will likely mean protection for a number of other species. However, the 15 reserves set up for tigers in India have not even adequately protected tigers, and poaching and encroachment threatens the ability of these reserves to protect many other species found within them. Another problem associated with the concept of mammalian umbrella species is that areas of species richness or endemism for other taxa, such as invertebrates, may not be within the designated core area of protection for a large mammal. A third issue of concern is that management for a single species, such as antipoaching efforts for tigers, may not satisfactorily protect other species whose main threats may involve other factors such as fire, fragmentation, or the spread of exotic species.

VII. PRESENT AND FUTURE TRENDS

Although mammals get a disproportionate amount of attention and funding for conservation efforts, the future for many species still looks grim. As of 1996, one-quarter of all mammal species were considered to be threatened. For a number of these mammals, a long-
term commitment will be needed scientifically, financially, and politically if they are to survive. However, species-based conservation efforts for mammals can have enormous costs. It has been estimated that conservation of the northern subspecies of the white rhino (Ceratotherium simum cottoni) runs about US$10,000 a year per rhino, while the cost over seven years for reintroduction of the golden lion tamarin was estimated at more than US$1.5 million. The cost of creating and maintaining a preserve that will protect populations of many mammal species (as well as other taxa) is only a fraction of that needed for species-based management.

Unfortunately, for many endangered mammals there is a desperate need for immediate and focused management efforts. There also is a tremendous need for more protected areas and better protection within the reserves themselves, and a need for directing conservation efforts toward nonprotected land, whether it be through zoning of public and private lands or the use of private ranches or communal lands. For this to succeed, efforts must also be directed toward educating local people about conservation issues, minimizing wild mammal–people conflicts and developing compensation schemes, and managing the threat of disease. In all cases, research and monitoring of wildlife populations and threats is critical, especially in situations where sustainable harvesting is being attempted.

IV. What We Know: Examples of Endangered Marine Invertebrates
V. What We Do Not Know: The Potential Scale of Endangerment

GLOSSARY

critically endangered: A species facing an extremely high risk of extinction in the wild in the immediate future.
dangerous: A species not critically endangered but facing a very high risk of extinction in the wild in the near future.
euryhaline: Able to live over a wide range of salinities, from brackish to fully marine waters.
planktotrophic: Larval forms of invertebrates that feed on plankton to survive and grow.
stenohaline: Able to live only in fully marine waters.
threatened: Vulnerable, endangered, and critically endangered species.
vulnerable: A species not critically endangered or endangered but facing a high risk of extinction in the wild in the medium-term future.

ALTHOUGH ONLY A FEW MARINE INVERTEBRATE SPECIES are known to be endangered, there may be hundreds to thousands of species actually at risk of extinction. The ability to determine the conservation status of such species faces considerable challenges. Habitat destruction, fisheries activities, and the introduction of exotic species are among the primary causes leading to the endangerment of marine invertebrates.

I. ENDANGERED MARINE ORGANISMS—CONSIDERATIONS AND DEFINITIONS

More marine organisms are threatened by increasing human pressures in the 21st century than ever before. Of the many enduring challenges in marine conservation science, one of the greatest is securing an objective understanding of extinction risk of individual species. With increasing attention paid in the world’s oceans to the broad concept of “threatened and endangered species”—attention cascading from similar concerns in terrestrial ecosystems—the question of perceived versus actual vulnerability of many marine animals and plants is a pressing one for scientists and conservationists.

In the following treatment one group of marine organisms—the invertebrates—is considered relative to endangerment and potential extinction. In turn, given their broad range of reproductive strategies, habitats, and susceptibility to human-induced extirpation, inver-
Endangered marine invertebrates may serve as model systems to understand endangerment in the broader array of marine life, including algae (seaweeds), seagrasses, vertebrates, bacteria, protists, and fungi.

What constitutes endangerment in marine invertebrates? The IUCN Red List (Baillie and Groombridge, 1996) considers three categories: critically endangered, endangered, and vulnerable species, all grouped under the broad aegis of threatened. Assignment of a species to one of these three categories is based on quantitative assessments (Table I). Information required includes temporal data (for example, rate of population decline, population fluctuations), spatial data (for example, extent of occurrence, number of populations), and population data (for example, size of population, number of adults). A species is critically endangered when “it is facing an extremely high risk of extinction in the wild in the immediate future”; a species is endangered when “it is not critically endangered but is facing a very high risk of extinction in the wild in the near future”; and a species is vulnerable when “it is not critically endangered or endangered but is facing a high risk of extinction in the wild in the medium-term future.”

There are other scales of endangerment as well, and these are parallel to scales of extinction. Local endangerment occurs when a species faces extinction in a small area or habitat. Regional endangerment occurs when a species faces extinction in a broad geographic region. Global endangerment occurs when a species faces extinction everywhere. Functional endangerment occurs when

**A. Declining Populations**
- Population decline rate at least
  - 80% in 10Y or 3G
  - 50% in 10Y or 3G
  - 20% in 10Y or 3G

Using either
  1. population reduction observed, estimated, inferred, or suspected in the past or
  2. population decline projected or suspected in the future based on
    a. direct observation
    b. an index of abundance appropriate for the taxon
    c. a decline in area of occupancy, extent of occurrence, or quality of habitat
    d. actual or potential levels of exploitation
    e. the effects of introduced species, hybridization, pathogens, pollutants, competitors or parasites

**B. Small Distribution and Decline or Fluctuation**
- Either
  - extent of occurrence
    - <100 km²
    - <500 km²
    - <2,000 km²
  - area of occupancy
    - <10 km²
    - <500 km²
    - <2,000 km²

and two of the following three:
  1. either severely fragmented (isolated subpopulations) or known to exist at a number of locations
  2. continuing decline in any of the following:
    a. extent of occurrence
    b. area of occupancy

continues
a species faces loss of its role in structuring a community (that is, influencing the diversity, distribution, or abundance of other species) or mediating energy flow in an ecosystem.

In practice, these categories may be expressed as a dichotomy between (1) species that have been demonstrably reduced to one or a few populations (whether adjacent or widespread) everywhere and thus face global extinction, and (2) species that have been demonstrably reduced in some locations but still maintain populations over a large area and thus face “only” local or regional extinction.

A final category of endangerment involves international transport and trade. Under Appendices I and II of the 1997 Convention on International Trade in Endangered Species of Wild Fauna and Flora (CITES), in terms of marine invertebrates, all species of giant clams (family Tridacnidae), the queen (pink) conch snail Strombus gigas, all corals (Scleractinia), as well as other Anthozoa (Coenothecalia, Stolonifera, and Antipatharia) and certain hydrozoan corals (Milleporina and Stylasterina) are listed. Appendix I species are considered “the most endangered” and include "all species threatened with extinction which are or may be affected by trade.” Appendix II includes “other species at serious risk . . . which although not necessarily currently threatened with extinction may become so unless trade is subject to strict regulation.” These CITES trade protected species may thus, in popular or legal writing, become endangered species, although many would not be so listed (as either critically endangered, endangered, or vulnerable) under

IUCN quantitative guidelines. As an example the North Atlantic coral *Lophelia pertusa*, which ranges to 1500 m depth from Scandinavia to the Mediterranean (and which can occur on the Norwegian shelf in deep water (270–310 m) in the form of coral reefs over 13 km in length, 10 to 35 m in height and up to 300 m in width) was reported in the popular press in 1999 as “endangered,” citing CITES listing of all corals, after being found on North Sea oil platforms. Awarding species protected status may provide certain benefits, such as regulated fisheries, regulated trade and transport, habitat protection, and so forth, even if the species is not close to extinction per se. Alternatively, very broad application of the concept of vulnerability to species that are not immediately threatened may decrease sensitivity to the issue of potential extinction and thus increase the difficulty in affording truly endangered species adequate protection.

II. WHY IS IT HARD TO KNOW IF A MARINE INVERTEBRATE IS ENDANGERED?

Knowledge of marine biodiversity is poor and getting poorer. The names, distribution, and ecology of most marine organisms are not well known. There are fewer professional systematists and biogeographers with every passing generation. It is thus difficult to assess the status of now uncommon and rare species—those that are becoming or have become endangered. And just as in terrestrial ecosystems, many species in the oceans may go extinct or become endangered before they are described. In familiar and relatively easily accessible marine environments in Pacific, Atlantic, and Gulf of Mexico seas, often more than half of the species encountered in certain groups are not known to science (Table II). Indeed, most of the species in the oceans are undescribed, even though the majority of the largest common species in shallow waters have been given Latin names. More generally, the last half of the 20th century, in parallel with increased interest in the scale of modern human-mediated change in the oceans, has been marked by decreased documentation of changes in the status, range, and natural history of marine invertebrates. Carlton et al. (1991) reported that a common species of intertidal snail along the New England coast became extinct about 1930, but the species remains listed as “common” in many modern seashell books. Gathering the precise data required under the IUCN guidelines (Table I) thus may often pose considerable challenges.

As a result, Carlton et al. (1999) were able to document only four species of marine snails that have become extinct in historical time. Roberts and Hawkins (1999) identified no further candidates among marine invertebrates for clear evidence of extinction. Turgeon et al. (1998) list no North American marine mollusks as endangered or threatened. Does this situation mean that marine invertebrates are generally “safe” or “immune” from extinction, or does this reflect our level of

Modified from National Research Council (1995).
knowledge of the conservation status of marine life? Modern authors have concluded that the latter is now the case, and that a ‘tip of the iceberg’ understanding of marine endangerment now exists.

III. WHAT CAUSES THE ENDANGERMENT OF MARINE INVERTEBRATES?

Both natural and human-mediated changes to the environment can lead to the endangerment and extinction of marine organisms. Examples of natural changes include volcanic eruptions destroying endemic island marine communities, tropical storm activity (such as hurricanes and monsoons) causing destruction of reef communities, and other severe weather systems, such as sustained winter freezing impacting temperate shore communities. While many cases of these natural impacts have been documented, none have been linked to the extinction or endangerment of any marine invertebrate species (although such may have occurred).

An example of the ocean-wide demise of a marine invertebrate by what may have been a natural series of events is the case of the eelgrass limpet Lottia alveus. This snail, which occurred from Labrador to New York, lived solely on the blades of the eelgrass Zostera marina. Between 1930 and 1933, 90% of the eelgrass in this region died due to a disease caused by the slime mold Labyrinthula zosterae. The last known population of the limpet occurred on Mt. Desert Island, in the Gulf of Maine, where in 1929 it occurred by the thousands. Lottia was a stenohaline species; however, its host, the eelgrass (with a broader physiological repertoire than the limpet) survived in brackish-water refugia below the salt tolerance of the slime mold. A distinct subspecies—or sibling species—of Lottia alveus survives in the North Pacific Ocean, from Alaska to British Columbia. It may be noted that the possibility remains that Labyrinthula was introduced to North America in some manner.

In an important lesson in understanding the relative susceptibility of marine organisms to extinction, another North American Atlantic eelgrass specialist, the sea slug Elysia catalaou, did not become extinct, because it, like the eelgrass, is euryhaline. Disease events that impact the host of specialized species could, in theory, lead to species endangerment as well, and it may be that for a period of time Elysia would have been regarded as a threatened species until the reexpansion and recolonization of eelgrass over the following decades.

Human-induced pressures on marine communities include fishing, chemical pollution, destruction of habitat, invasions of nonindigenous (exotic) species, and atmospheric chemical alterations leading to global climate change. We know a great deal about many of these pressures. However, our record of changes in the distribution and abundance of marine life in the 19th and 20th centuries is inverse to our record of the rapid increase of these anthropogenic activities.

Overall, habitat destruction, fisheries (both overexploitation and the secondary impacts of fishing) and the invasion of nonindigenous (exotic) species are held to be the primary causes of endangerment to marine organisms. The global extinction of three species of marine mollusks, the southern California rocky shore limpet Calliellula edmitchelli, the Chinese periwinkle Littoraria fluminea, and the southern California mudflat hornsnail Cerithidea fascata, have all been linked to habitat destruction. While overfishing has not yet been linked to the endangerment of a marine invertebrate, vast declines in marine invertebrate populations around the world due to fishing and fishing activities are increasingly recorded. The North Atlantic whelk Buccinum undatum is now absent in areas of the southern and central North Sea and the Dutch Wadden Sea where it was abundant in the 1970s. Overfishing, combined with a disease of unknown origin, have led to such vast declines in commercial sponges in the Mediterranean Sea that some workers consider certain species to be on the ‘brink of extinction.’ Here again regional extinction needs to be distinguished from global extinction, although unrelenting fisheries within an enclosed basin could lead these extinction states to synonymy.

Trawling on the sea floor (dragging nets, chains, bags, scoops, and a plethora of similar devices on the bottom) represents a combination of both habitat destruction and fisheries and has extended the reach of human perturbation well onto the continental shelves of the world, far from the marine habitats that have been classically viewed as those able to be destroyed.

While trawling is particularly a concern of the 20th and 21st centuries, the roots are deep, as they are with many human-induced pressures on the oceans. As early as 1370 the Commons petitioned the King of England ‘that the great and long iron of the wondyrchoun [a net] runs so heavily and hardly over the ground when fishing that it destroys the flowers of the land below water there’ (from the Records of the Parliament in the Reign of Edward III). It seems plausible, given some six and more centuries of trawling in selected regions of the world, that certain invertebrate species would have been heavily impacted. However, no reports of
endangerment or extinction are in hand, a situation resulting, as discussed earlier, from a lack of knowledge of the distribution of threatened species in benthic habitats on the sea floor (and noting again the number of undescribed species found in shelf habitats [Table II]).

Underscoring the probability that marine benthic invertebrates may be endangered by consistent habitat destruction (and emphasizing the difficulty of recognizing such species) is the discovery that a large fish, the barndoor skate Raja laevis, formerly common and widespread in the Northwest Atlantic Ocean, virtually disappeared in the 1990s from benthic trawls, when it used to be common as trawl bycatch. Given that the demise of Raja, a 1.5 m long fish, was not recognized until 1999, the chances of detecting the loss of much smaller organisms such as most invertebrates is all the more unlikely.

IV. WHAT WE KNOW: EXAMPLES OF ENDANGERED MARINE INVERTEBRATES

The IUCN ‘Red List’ lists 13 marine invertebrate species as high-profile threatened species: one species is considered endangered, two critically endangered, and ten vulnerable. Evaluating whether these species (10 mollusks, 1 crab, 1 sea anemone, and 1 seafan) are globally threatened is often a challenge, as no published data are cited for any listing. Often species are suggested for global listing based on local or regional extinctions of populations or based on the rate at which local or regional populations are discovered to be in decline. While such observations may be a harbinger for what may eventually become global concerns, the data may be lacking to understand the full extent of endangerment. As examples, the status of 4 of these 13 species is as follows:

- The tiny Northeastern Pacific crab Parapinnixa affinis is listed by IUCN as ‘endangered’. It lives in bays in shallow, perhaps largely intertidal, mud bottoms, as a commensal in the tubes of terebellid polychaete worms. It was first collected in 1895 in what was to become Los Angeles–Long Beach Harbor, and as late as 1932 it was collected at several locations between Los Angeles and San Diego. No further material from southern California has surfaced. Given the extraordinary modifications of these embayments in the 20th century, with little or no semblance of original habitat often remaining, the demise of this (and many other) species would not be unexpected. However, it may remain common in similar habitats of Baja California, the Gulf of California, and further south, sites that remain largely unexplored. P. affinis was ‘rediscovered’ in one such location, in Tortugas Bay, southwestern Baja California, in 1987. It thus may be an example of local and regional extinction.

- The salt marsh sea anemone Nematostella vectensis is listed by IUCN as ‘vulnerable,’ also a high-profile endangerment category. This species occurs, often in large numbers, in salt marsh pools in the Northwest Atlantic Ocean from Nova Scotia to the Gulf of Mexico and in the Northeast Pacific Ocean from Washington to California. It also occurs in England, its type locality (but not apparently otherwise in Europe); given its widespread distribution in North America, it may be introduced in the Eastern Atlantic Ocean. In England it is considered rare (based on localized populations and declining habitat, although where found it may be abundant) and is given protected status. The habitat of this anemone has, throughout portions of its range, been fundamentally altered (if not completely removed), and thus the abundance of this anemone has inevitably been reduced, but it remains common in many areas. It too would appear to be an example of local extinction.

- The giant clam Tridacna derasa is listed (along with other species of Tridacna) as vulnerable. These clams characterized many shallow-water reef environments up to the mid-20th century, before commercial removal caused their widespread disappearance and population declines. There is thus no doubt that both the range and abundance of a number of Tridacna species have been severely modified, and indeed certain populations are extinct. However, T. derasa, as an example, remains widespread throughout a vast area of Australasia and the Indo-Pacific and is widely used in mariculture.

- The sea fan Eunicea verrucosa is listed as vulnerable. It lives at sublittoral depths of 10 m and deeper on sheltered rocky bottoms. The species is widely distributed from northern Europe to Africa, and it remains common in a number of sites.

All of these species have suffered at the hands of habitat destruction (Parapinnixa, Nematostella) or human exploitation (Tridacna, Eunicea). Because of knowledge lacunae and provincial perspectives, they illustrate the difficulty in ranking threat status and in attempting to assess whether local and regional extinctions imply impending global extinction. There are many

Underscoring the probability that marine benthic invertebrates may be endangered by consistent habitat destruction (and emphasizing the difficulty of recognizing such species) is the discovery that a large fish, the barndoor skate Raja laevis, formerly common and widespread in the Northwest Atlantic Ocean, virtually disappeared in the 1990s from benthic trawls, when it used to be common as trawl bycatch. Given that the demise of Raja, a 1.5 m long fish, was not recognized until 1999, the chances of detecting the loss of much smaller organisms such as most invertebrates is all the more unlikely.

The IUCN ‘Red List’ lists 13 marine invertebrate species as high-profile threatened species: one species is considered endangered, two critically endangered, and ten vulnerable. Evaluating whether these species (10 mollusks, 1 crab, 1 sea anemone, and 1 seafan) are globally threatened is often a challenge, as no published data are cited for any listing. Often species are suggested for global listing based on local or regional extinctions of populations or based on the rate at which local or regional populations are discovered to be in decline. While such observations may be a harbinger for what may eventually become global concerns, the data may be lacking to understand the full extent of endangerment. As examples, the status of 4 of these 13 species is as follows:

- The tiny Northeastern Pacific crab Parapinnixa affinis is listed by IUCN as ‘endangered’. It lives in bays in shallow, perhaps largely intertidal, mud bottoms, as a commensal in the tubes of terebellid polychaete worms. It was first collected in 1895 in what was to become Los Angeles–Long Beach Harbor, and as late as 1932 it was collected at several locations between Los Angeles and San Diego. No further material from southern California has surfaced. Given the extraordinary modifications of these embayments in the 20th century, with little or no semblance of original habitat often remaining, the demise of this (and many other) species would not be unexpected. However, it may remain common in similar habitats of Baja California, the Gulf of California, and further south, sites that remain largely unexplored. P. affinis was ‘rediscovered’ in one such location, in Tortugas Bay, southwestern Baja California, in 1987. It thus may be an example of local and regional extinction.

- The salt marsh sea anemone Nematostella vectensis is listed by IUCN as ‘vulnerable,’ also a high-profile endangerment category. This species occurs, often in large numbers, in salt marsh pools in the Northwest Atlantic Ocean from Nova Scotia to the Gulf of Mexico and in the Northeast Pacific Ocean from Washington to California. It also occurs in England, its type locality (but not apparently otherwise in Europe); given its widespread distribution in North America, it may be introduced in the Eastern Atlantic Ocean. In England it is considered rare (based on localized populations and declining habitat, although where found it may be abundant) and is given protected status. The habitat of this anemone has, throughout portions of its range, been fundamentally altered (if not completely removed), and thus the abundance of this anemone has inevitably been reduced, but it remains common in many areas. It too would appear to be an example of local extinction.

- The giant clam Tridacna derasa is listed (along with other species of Tridacna) as vulnerable. These clams characterized many shallow-water reef environments up to the mid-20th century, before commercial removal caused their widespread disappearance and population declines. There is thus no doubt that both the range and abundance of a number of Tridacna species have been severely modified, and indeed certain populations are extinct. However, T. derasa, as an example, remains widespread throughout a vast area of Australasia and the Indo-Pacific and is widely used in mariculture.

- The sea fan Eunicea verrucosa is listed as vulnerable. It lives at sublittoral depths of 10 m and deeper on sheltered rocky bottoms. The species is widely distributed from northern Europe to Africa, and it remains common in a number of sites.

All of these species have suffered at the hands of habitat destruction (Parapinnixa, Nematostella) or human exploitation (Tridacna, Eunicea). Because of knowledge lacunae and provincial perspectives, they illustrate the difficulty in ranking threat status and in attempting to assess whether local and regional extinctions imply impending global extinction.
species, however, that may be certainly endangered. We discuss examples here (Tables III and IV).

The invertebrates—and all species—that live in marine habitats most influenced by human activity have sustained the most damage. It is in these habitats that endangered species are especially to be sought. These include salt marshes, mangroves, estuaries, lagoons, beaches, dunes, the supralittoral (maritime or strand line) zone, and seagrass beds. Especially vulnerable are habitats within regions that are now fragmented remnants of their previous extent. It is estimated that approximately half of the world's salt marshes and mangroves have been destroyed and along with them, of course, an untold number of species. Seagrasses—particularly the estuarine species, such as the eelgrass *Zostera*, turtle grass *Thalassia*, shoal and star grasses *Halodule*, manatee grass *Syringodium*, and others that support unique species of snails, chitons, and other invertebrates precisely adapted to their blades—serve as particularly compelling harbingers of threat to coastal marine biodiversity.

Several examples are available of endangered species living where expanding human populations impinge on these fragile shoreline habitats. Two small sea slugs, the anaspidean sea hare *Phyllaplysia smaragda* and the sacoglossan slug *Stiliger vossi*, known only from Florida lagoons, have been missing for many years. *Phyllaplysia* was first described in 1977 and last found in 1981. It was only known from the Indian River Lagoon of eastern Florida. It ate epiphytic algae growing on the manatee grass *Syringodium*, a plant subsequently obliterated from the sea slug's type locality (although the plant remains widespread elsewhere in southern waters, including Florida and the Caribbean, and in many of which locations *Phyllaplysia* has been sought unsuccessfully). *Stiliger*, another herbivore, was first and last collected in 1980 in Biscayne Bay, southeast Florida, despite years of subsequent searching. While subtropical Caribbean lagoons and bays remain to be thoroughly explored, there appears to be little doubt that these slugs have been and remain at risk because of living in habitats proximal to rapidly expanding human populations.

The false limpet *Siphonaria compressa* is represented by what is probably one last remaining population in the Langebaan Lagoon on the west coast of South Africa. It is listed by IUCN as critically endangered. Little is known of its life history (although it may have non-planktonic development), population dynamics, or environmental tolerances. It is restricted, however, to living on the eelgrass *Zostera capensis*, the width of whose narrow blades it matches (thus the name of the limpet). In this regard, it is an ecological equivalent of the northern hemisphere true limpet *Lottia alveus*, which similarly was, in the North Atlantic Ocean, restricted to the eelgrass *Zostera marina*. Although Langebaan Lagoon is part of a national park and is a site identified under the Ramsar Convention on Wetlands of International Importance, regional harbor development leading to pollution, the introduction of nonindigenous species, severe weather events, disease, or other phenomena could threaten this last stand of *Siphonaria*.

An unusual example of an endangered taxon in a coastal habitat is the small (1.0 cm) talitrid amphipod crustacean (*beach hopper*) *Transorchestia enigmatica*. It is an intertidal species, eating decaying plant material, known only from a single beach approximately 0.8 km in length on the shores of an estuarine lagoon (Lake Merritt) in the middle of a densely urbanized region (Oakland) of San Francisco Bay. It is closely related to the South Pacific Ocean species *Transorchestia chilliensis*, which is known from New Zealand and Chile. *Transorchestia enigmatica* is presumed to have been carried into San Francisco Bay, perhaps in the 19th century, in the dry (beach) ballast of ships from the southern hemisphere. However, no populations of *T.

* If not already extinct.
Another risk group are those species with relatively limited distributions (even if such may be an ocean basin!) under heavy, inexorable extraction pressure. Under this category we find one of the most compelling examples of endangerment among invertebrates in the oceans.

The white abalone, Haliotis sorenseni, is a large gastropod (up to 22 cm long) which formerly ranged from Point Conception in southern California to the islands of central Baja California, on low-relief rocky reefs in sublittoral waters to depths of about 65 m. Its modern postfisheries range, especially its northern limits, is not known. A number of species of abalone, a widely sought after mollusk, occur along the Pacific coast of North America and have since the 1850s attracted sport and commercial fisheries both for the shell and the meat. Marked depletion of certain species on the California coast was noted by the turn of the 20th century and regulatory laws were passed in 1903 to set size limits. Keep noted in 1904 that the “persistent warfare” against the red abalone Haliotis rufescens had rendered large specimens rare compared to about 1884. Edwards (1913) reported that the green abalone Haliotis fulgens and the pink abalone Haliotis corrugata, which about 1893 occurred piled four and five deep on rocks near Avalon, Santa Catalina Island (southern California), were by 1913 entirely gone.

The white abalone H. sorenseni was not described as a distinct species until 1940. It is a deeper water species that entered the commercial fishery only later, after shallow water abalone were exhausted. Thus there are no comparable early records of depletion. However, in remarkable parallel with the reports of Edwards on the green and pink abalones are the much later findings of Davis et al. (1998) who consider white abalone to be on the brink of extinction. Davis and colleagues searched more than 107,000 square m of white abalone habitat on the Channel Islands, the species’ historical center of abundance. By the early 1990s at depths of 25 to 42 m (where in the 1970s mean densities were 2000 to 10,000 abalone per hectare) mean white abalone densities had decreased to 1.6 ± 0.5 per hectare. In 1996 and 1997, at depths of 27 to 67 m, densities had further dropped to extremely low numbers, 1.0 ± 0.4 per hectare. Commercial harvests virtually ceased after the 1970s, but no fishery-independent assessment of white abalone populations was made until 1992 to 1993, in the meantime the fishery remained open until 1996, based on a minimum harvest size of 15.3 cm and a closed season during spawning. All surviving white abalone known in the wild are adults and dying of old age. Davis et al. suggest that while spontaneous recovery is highly unlikely, even in the absence of any further harvesting, a mariculture program may be able to save the species from global extinction.

White abalone produce planktotrophic larvae. However, as the last known recruitment event occurred in the late 1960s or 1970s, and with population densities now far below 1 per square m, successful fertilization may now be impossible, and complete reproductive failure of the species appears to be at hand. Unless unknown populations exist in refugia in deeper water (abalones are rarely if ever seen below 67 m) or populations of sufficient size exist to the south in Mexican waters, the total size of the white abalone population may now be fewer than 1000 individuals.

The white abalone offers the following lessons about the pathway to endangerment: a combination of restricted habitat (a narrow sublittoral zone), the ability to discover and remove most individuals by advanced diving technology, a severe disruption of the life history of the species such that sporadic recruitment (that likely relied on sufficient adult densities) was interrupted, and the lack of a fishery management framework have all led to the demise of this once common open ocean species. No juvenile abalone have been found in many years. An intensive, focused fishery on the white abalone began only about 1965 but vanished 35 years later, perhaps with the mollusk itself.

There are several other guilds of at-risk marine organisms as well. Mentioned earlier were species restricted to an extinguishable (but not necessarily itself endangered) living host, which could be impacted by a disease or other agent. The demise of the eelgrass Zostera marina under this category. Endangered species would also include, of course, those invertebrates that are commensals, parasites, and symbionts of other endangered marine organisms (Table IV). Finally, the invasion of exotic species may lead to at least local or regional extinctions (Geller, 1999). The native mussel Mytilus trossulus, once abundant in southern California both historically and in native American shell middens, was rendered virtually regionally extinct by the invasion in the 20th century of the Mediterranean look-alike mussel Mytilus galloprovincialis.

V. WHAT WE DO NOT KNOW: THE POTENTIAL SCALE OF ENDANGERMENT

Given the extent of the modification, destruction, devastation, and extirpation that has characterized coastal
marine environments over the past 1000 and more years, hundreds or thousands of species of marine invertebrates may in fact be endangered, as opposed to the few cases reviewed here or listed under IUCN. For example, it has been estimated that given that a minimum of 5% of the world’s coral reefs have been degraded to a nonreef state, and based on estimates of coral reef biodiversity per unit area, as few as 1,000 species of coral reef invertebrates may have already become extinct in modern times (although, as with many tropical forest ecosystems, we have no records of these species, many of which may not have been described before going extinct). It follows that many thousands of coral reef invertebrates may be endangered as well, given that coral reef destruction continues largely unabated in many parts of the world.

More generally, the demise of the white abalone offers a striking counterpoint to the ancient assumption of the invulnerability of marine life to exhaustion by human extraction. Lamarck in 1809 wrote,

Animals living in the waters, especially the sea waters . . . are protected from the destruction of their species by man. Their multiplication is so rapid and their means of evading pursuit or traps are so great, that there is no likelihood of his being able to destroy the entire species of any of these animals.

These words were echoed by Byron in 1818 in a similar fashion,

Man marks the earth with ruin, his control Stops with the shore.

These turn-of-the-19th century views of the oceans were clearly incorrect and at the turn of the 21st century the reverse now appears to be true.

Bibliography

THE GROWING PUBLIC CONCERN about endangered plants is well founded. It is estimated that there are between 235,000 (Raven et al., 1986) and 270,000 (IUCN, 1998) species of vascular plants (including ferns and fern allies, gymnosperms, and flowering plants) in the world today; two-thirds of these species are found in the tropics (Raven et al., 1986). The World Conservation Union (IUCN, 1998) currently lists 33,798 species (12.5% of the world’s flora) as threatened, and 6,522 species of plants (2.4% of the world’s flora) as endangered. Threatened plants are found among 369 plant families in 200 countries. The U.S. Fish and Wildlife Service reports 540 endangered species and 130 threatened species of flowering plants in the United States (U.S.) as of November 30, 1998.

I. INTRODUCTION

Extinction has always played an important role in nature: 95 to 99% of all species that ever existed are now extinct. It is the current rapid rate of extinction that has many plant ecologists worried. Worldwide, as many as 654 species of plants have gone extinct since A.D. 1600 (Heywood, 1995). In this time period, about 110 plant species may have gone extinct in Hawaii according to records of the U.S. Fish and Wildlife Service and The Nature Conservancy. Estimates of plant extinctions in the continental United States range from below 25 (IUCN, 1998) to above 90 (Davis et al., 1986; Flather
et al., 1994). The discrepancy in estimates is due to incomplete systematic surveys, limited monitoring activities, and poor information on viable seed banks. Estimates of extinctions in other countries include 71 plant species in Australia, 53 in South Africa, 47 in Mauritius, and 23 in Cuba. Three endemic species of ebony ( Diospyros spp.) went extinct in the Mascarene Islands before they were described. Nuttall's mudwort (Micranthemum micranthomodes) had been recorded in Delaware, Maryland, New Jersey, New York, Pennsylvania, Virginia, and the District of Columbia, but, despite extensive searches it has not been seen since 1941. The single individual of Dichotera dohmi, which clings to life in western Ecuador (Gentry, 1986), may be the next victim of accelerated extinction.

Estimates of future plant species extinctions vary widely. Raven et al. (1986) estimated that about 40,000 tropical plant species may go extinct in the wild within the next several decades. The New York Botanical Garden suggests that about 700 of the more than 2000 species of threatened and endangered plant species in the United States may be extinct in the next 10 years. The Center for Plant Conservation reported that 680 U.S. plant species were critically endangered, with approximately 253 species estimated to become extinct in 5 years and 427 species to become extinct in 10 years (based on unpublished data in 1988). Today, more than 10 years later, there is little evidence of these mass extinctions, but the concern may still be well founded in several areas.

Hawaii provides a good example of endangered plants. Up to 47% of the Hawaiian flora may meet the criteria for official listing by the U.S. Fish and Wildlife Service, with as many as 16% immediately threatened with extinction (see the Missouri Botanical Garden website listed in the Bibliography). The genus Hibiscadelphus in Hawaii includes only six species (with two extinct species) with a total of 14 live individuals, and one species with only one individual (Cody, 1986). The Hawaii Endangered Plant Task Force, which includes many federal, state, and non-government partners, now tracks 997 threatened, endangered, and rare plant species.

There is a growing backlog of candidates for listing as endangered species. Between July, 1976, and August, 1992, about 231 species per year were added to the U.S. endangered species list. In the second half of that 16-year period, 33 species per year were added to the list (Flather et al., 1994). More than 200 plant species are being petitioned for future listing in the United States. It has been said that “all species are rare somewhere” (Orians, 1997), because most plant species have larger populations in well-suited habitats and smaller populations in marginal or sub-optimal habitats. Many threatened vascular plants in Finland were found to be rare largely because the species were in marginal rather than suitable habitat (Cropper, 1993). Along with the increasing threats of rapid environmental change, habitat loss, contaminants, and invasive exotic species, we may face an uphill battle in protecting our treasured botanical resources in these sub-optimal habitats.

Maintaining biodiversity requires a considerable understanding of rarity and the processes and stresses that promote the endangerment of certain plant species. This article reviews the kinds of rarity, patterns of endangerment, causes of endangerment, consequences of rarity, and legal mandates to protect endangered plant species. It then provides selected examples of endangered plants and concludes with the management and social implications of protecting endangered plants.

II. KINDS OF RARITY

There are many published definitions of rarity. In an extreme example, DuMond (1973) stated nine criteria for rarity, including species that are: (1) found out of its expected context; (2) particularly subject to extinction or severe reduction in total population size by human activities that have already caused a significant population reduction; (3) found only in a very specific habitat of limited occurrence; (4) thought to be a relic of a no-longer extant vegetation association; (5) an indicator of a unique extant vegetation association; (6) recognized as an example of a wide, disjunction pattern; (7) at its natural distribution limits within the area in question; (8) known to be introduced and has become naturalized only on a very small scale; or (9) does not consistently occur as a member of any particular natural plant community. Gaston (1997) described rarity in another way, noting that rare species can be delimited on the basis of one, two, or at most a few of the following variables: abundance, range size, habitat specificity (habitat occupancy), temporal persistence (e.g., taxon age), threat (probability of, or time to, extinction), gene flow, genetic diversity, endemism, and taxonomic distinctness. Rare species in the IUCN Red Book (1998) are described in terms of population size rather than an assessment of extinction risk, which is reserved for threatened and endangered status. The Nature Conservancy and associated network of Natural Heritage Programs rate species endangerment based on five levels of global rarity (i.e., G1, G2, G3, etc.), national rarity (N1, N2, etc.), and state rarity (S1, S2, etc.).
The kinds of rarity that concern conservation biologists relate specifically to the potential vulnerability to extinction. Commonly recognized kinds of rarity (Rabinowitz, 1981; Cropper, 1993) include species with:

- Small populations, large geographic range, and occurrences in several habitats. For example, American chaffseed (Schwallrea americana) had a historical distribution from Mississippi to Massachusetts. It resides now in 20 relatively small populations in five states, with the greatest populations in South Carolina. It can survive in several vegetation types as long as there is enough light in the understory. Fire suppression, which allows for succession and canopy closure, threatens several Schwallrea populations. Another example is Hypochoris maralana, which has small populations over a wide range in Great Britain.

- Large populations, large geographic range, but occurrences in specific habitats. For example, several grassland species of Calochortus (lilies) in California have large populations following wildfires. They were thought to be far more widespread prior to a century of fire suppression and encroachment of shrubs into grassland habitats. Sparse populations in a large geographic range but in specific habitats. For example, Pulstum madsoni grows only on rocky outcrops and always in sparse populations, but it occurs in Australia, New Zealand, and Easter Island (Cropper, 1993).

- Small geographic range, but locally abundant in specific habitats. For example, the 48 endemic species of Bignoniaceae in Amazonia have a total home range of only a few thousand square kilometers, but some of these species are locally abundant in restricted habitats (Gentry, 1986). A specific example in Scotland is Primula scotica, which has a tiny range with a few large populations.

- Small geographic range, and sparse in specific habitats. This may be the most critical type of rarity, for small populations restricted to small and specific habitats are highly vulnerable to extinction. For example, the scouring of a new stone quarry in South Africa ended life in the wild for Moraea loubservi, a small, sparsely population iris (Sterner, 1993).

- Small populations of concern in any region despite populations elsewhere. For example, many floristically poor northern European countries typically have 200 or more plant species listed as threatened or endangered. However, many of these species invaded broadly since the last Ice Age, and they are buffered from extinction with widely scattered populations in several countries (Davis et al., 1986).

- Small populations of new species. For example, a newly discovered species of Calyptranthes from El Yunque, Puerto Rico, has a population of four trees, and Auerodendron pauciflorum from Quebradillas and Calyptranthes liquitissimus from the Luquillo Mountains have only five individuals each (Cody, 1986).

Generally, species may be ranked for protection based on overall rarity, magnitude of potential threats to populations, and the immediacy of the threats. Thus, a monotypic genus with high-magnitude and imminent threats might receive a higher priority ranking than a subspecies with moderate or non-imminent potential threat.

III. ENDANGERMENT PATTERNS

Slightly over 90% of threatened plants are single-country endemics. Species with restricted ranges face the greatest threat of extinction. It follows that endemic plant species on islands appear to be the most highly endangered. About 93% of the plant species on the Canary Islands are endemic, and 50% are considered endangered (Cody, 1986). Senecio heritieri, for example, is restricted to a small area of rocky slopes on the south coast of the island of Tenerife, one of the Canary Islands. On Crete, two-thirds of the 135 endemic species are endangered (Cody, 1986). Compare these numbers to those of the entire United States, where there are about 20,000 plant species of which 2,050 species are rare and threatened.

About half the plant species in Mediterranean climate areas (parts of California, South Africa, Australia, and the Mediterranean basin) are narrow endemics that dominate the threatened and endangered species lists in their various countries (Fig. 1) (Davis et al., 1986). California, for example, contains 869 endemic species of the 2,050 species on the U.S. rare and threatened list (Davis et al., 1986). Chile has 30 forest tree species; 47 of these species are endemic and 38 species are listed as endangered, vulnerable, or rare.

Over half of the rare and endangered plants of the continental United States grow within the borders of 12 western states (Arizona, California, Colorado, Idaho, Montana, Nevada, New Mexico, Texas, Utah, Oregon, Washington, and Wyoming; Fig. 2) (Flather et al., 1994). However, among U.S. states Hawaii is the hot
FIGURE 1  Distribution of rare plants in the world. Data from the IUCN Red List for 1997 (IUCN, 1998).

FIGURE 2  Distribution of rare plants in the continental United States. The “top 10” continental states for rare plants include six western states, and California clearly dominates. [From C. H. Flather et al., BioScience 48(5), pp. 365–376. ©1998 American Institute of Biological Sciences.]
Thus, Eriogonum shrubs of the species-rich genera prone to extinction: 72 of 268 native species are very (IUCN, 1998). Cacti in the United States are particularly less adapted to today’s rapidly changing environment. Sporums, containing relatively ancient species, may be of rare species than do species-poor genera. Gymnosperms, containing relatively ancient species, may be less adapted to today’s rapidly changing environment (IUCN, 1998). Cacti in the United States are particularly prone to extinction: 72 of 268 native species are very rare (Benson, 1982). In California, shrubs and subshrubs of the species-rich genera Arctostaphylos, Ceanothus, Eriogonum, and Ribes have a higher proportion of threatened and endangered plants relative to their proportion in the flora (Cody, 1986). Curiously, some rare plant habitats may have human origins. Some moorlands, or blanket bogs, in western Europe were created around 7,700 years ago by human activities of burning and grazing. These heathlands and grasslands today support many endangered plant species.

IV. CAUSES OF ENDANGERMENT

There are several natural causes of rarity that lead to endangerment. Ancient taxa, like cycads, are thought to be prone to extinction as they cling to increasingly shrinking relic habitats. New taxa, resulting from recent speciation, are thought to be susceptible to extinction because they have not had time to spread in distribution. Rare species generally lack an ability to rapidly colonize areas and they are often poor competitors. Many rare species are edaphically restricted to specific soils or geology. However, based on recent rates of extinction, natural causes of rarity (individually or combined) are no match for human-related causes of endangerment. Species usually become endangered because of multiple, human-related causes. The overwhelming cause of plant species endangerment is habitat loss, directly linked to agriculture, forestry, and urbanization. Remaining small populations have a higher risk of extinction (local extinction) or extinction. Coinciding with habitat loss is reduced habitat quality related to invasive species, grazing, and other land-use changes (Flather et al., 1994). There are many examples of habitat loss to choose from. In the wetter forested Sierra Madres of Mexico, Guatemalan fir (Abies guatemalensis) or Pinus bete trees are considered endangered from over-exploitation of old-growth forests, land-use change, and livestock grazing (Burton, 1991).

Persea theobromifolia, once an important timber species in western Ecuador, has been reduced to fewer than 12 trees at Rio Palenque (Centry, 1986). In the United States Burton (1991) reported that only 1% of the 1,036,000 km² (400,000 mi²) of tallgrass prairie remains, now existing in isolated patches and small nature reserves. Over half of all continental U.S. wetland and aquatic habitats have been destroyed. Fire suppression and succession, invasive exotic plants, and habitat fragmentation will make it increasingly difficult for rare species to persist. Causes of rarity vary by region. Though habitat loss was generalized as an overall problem, agricultural development was specifically noted in the southern Appalachian region, whereas urban development and forest clearing were specifically noted in Florida. In the Gulf Coast areas, shoreline modification and development were specifically noted in endangerment patterns (Flather et al., 1994).
Commercial exploitation is also a problem. Cacti in the southwestern United States are a prime example. Legislation regulating the collection of cacti in Arizona and California date from 1929. Yet, in a single year, over half a million small cacti were illegally collected for sale in the United States, Japan, and Europe (Burton, 1991). One of the two colonies of the 2.5-cm-diameter Nellie Cory cactus (Coryphantha minima) was completely eliminated by thieves in the 1960s. The rarest species demand the highest prices from collectors. Rare orchids are plucked one by one by various “collectors.” Some threatened orchids in India, such as Paphiopedilum druri, Dendrobium pauciflorum, D. nobile, and Diplomeris hirsuta, are used for medicinal purposes. As such, they are facing increasing pressure from growing and aging human populations.

Natural environmental change can both cause and maintain rarity. Cropper (1993) reported that some rare species, such as Leptothyrsa gazesi in Australia, are observed only following natural fire. A riparian herb, Collomia rawsoniana, required periodic high and low streamflows to persist. Likewise, disruption of the natural hydrology of Lake Okeechobee, the largest lake in Florida, has led to the endangered listing of Caesalpinia okeechobensis. Land management decisions can obviously upset required disturbance patterns. Fire suppression activities and flood control will likely increase the rarity of such species.

The introduction of exotic grazers such as goats, pigs, rabbits, and sheep often leads to devastated native floras. For example, 87 of the 49 native plant species on St. Helena Island in the south Atlantic Ocean are now rare or threatened. The island was once dominated by beautiful forests of St. Helena ebony (Trichetta melanoxylon). Goats were introduced on the island in 1513, and the goat population skyrocketed by 1588. Goats ate ebony seedlings and humans used mature trees as fuel, so by 1810 the forests were destroyed and the ebony was extinct. About 260 naturalized exotic plant species were also introduced to the island (Davis et al., 1986).

Introduced rabbits have greatly threatened Acacia corte in arid western New South Wales, Australia (Cropper, 1993), and nearly decimated Dudleya truxillae (ironically called the Santa Barbara live-forever) on Santa Barbara Island off California (Benseler, 1987). Hawaii’s beautiful Haleakala silversword (Argyrocephalum sandwicense ssp. macrocephalum), with a flower stalk up to 2 m tall, almost went extinct in the 1920s due to vandalism and grazing by introduced cattle and goats. Like many endangered plant species, several additional threats must be held at bay. A major effort in Hawaii is under way to protect the habitat of the Haleakala silversword from invasive exotic plants (Verbascum thapsus, mullein; and Pennisetum setaceum, fountain grass) and the Argentine ant (Iridomyrmex humilis). The Argentine ant poses a significant threat to native pollinators of the silversword.

Competition from invasive exotic plant species may be a major contributor in the future to native plant endangerment. Large, nearly pure stands of exotic purple loosestrife (Lythrum salicaria) have directly influenced the endangered small spikerush (Eleocharis parvula) in New York and Long’s bulrush (Scirpus longiz) in Massachusetts.

V. CONSEQUENCES OF RARITY

The most obvious consequence of rarity is extinction. Charles Darwin, like many naturalists of his time and since, recognized that rarity often preceded extinction. Small populations of sessile organisms are vulnerable to catastrophes. Landslides, fire, flooding, hurricanes, and other disturbances can simply wipe out populations. Small populations of vascular plants are also vulnerable to breeding problems from higher variability in breeding success caused by inbreeding. Inbreeding has been documented in several localized endemics such as Limnanthes bakeri, a vernal pool species in Mendocino County, California. In contrast, a common congener Limnanthes douglassii reproduces almost exclusively by cross-fertilization. Stephanomeria malheurensis, a plant species confined to one small hilltop in Burns, Oregon, is auto-fertile, whereas widespread congeners are not. Reproductive failure is not uncommon in sparse species. Lower genetic variation in small populations may also make them more vulnerable to rapid environmental change.

Not all small populations march rapidly towards extinction. Many rare plant populations can persist for centuries and millennia. Sparse populations can often avoid pathogens and herbivory: Pinus ponderosa, which may have been restricted to small refugia in Arizona and New Mexico at the end of the last Ice Age, has become the most widespread pine in the western United States; it now occurs from Mexico to Canada, and from California to Nebraska. Other small populations may speciate (form new species). For example, two species of Ranunculus in alpine areas of the North Island of New Zealand (R. verticillata and R. insignis) have given rise to R. nivicola.
VI. LEGAL MANDATES TO PROTECT ENDANGERED PLANTS

A. Policy and Legal Mandates throughout the World

The International Plant Protection Convention held in Rome in 1951 set forth recommendations for the protection and promotion of plant life throughout the world. Since then, the International Union for Conservation of Nature and Natural Resources (IUCN; now known as the World Conservation Union) has taken center stage in the protection of the world’s flora. The IUCN Plant Red Book strongly defines “endangered species” as a species in danger of extinction and whose survival is unlikely if the causal factors (e.g., over-exploitation, extensive habitat destruction) continue operating, “including taxa whose numbers have been reduced to a critical level or whose habitats have been so drastically reduced that they are deemed in immediate danger of extinction” (IUCN, 1998). It also identifies and tracks “vulnerable species” as those “believed likely to move into the endangered category in the near future if the causal factors continue operating.” Finally, it tracks “rare species”—taxa with small world populations that are not presently endangered or vulnerable, but are at risk.” These IUCN classifications are determined by scientists and government officials around the world and classified species are not necessarily afforded legal protection after designation (Stermer, 1995).

Several countries have policies or legislation that protect endangered plant species. Following the Convention on International Trade in Endangered Species (CITES) of Wild Flora in 1973, 113 countries have agreed not to trade certain threatened species. Many countries augment these agreements with additional legislation. For example, the Mauritius National Plant Protection Legislation (the Plants Act of 1976) and the Forest and Reserves Act (1983) legally protect endangered species and habitats in the territories of Mauritius. Enforcement of endangered species laws and policies in many countries is generally considered to be well-intentioned but weak.

B. The United States Endangered Species Act

The intent of the U.S. Endangered Species Act of 1973 (16 USC1531-1543) is to prevent further decline and help restore endangered and threatened species and the habitats upon which such species depend and to “provide a means whereby the ecosystems upon which endangered species and threatened species depend may be conserved” (Greenwalt and Gehenger, 1975). Thus, the Act recognizes the inseparable link between protecting a species, its habitat, and the surrounding ecosystem. The Act also provides broad-ranging protection for all species threatened with extinction in the “foreseeable future.”

The Act makes the “taking” of endangered species anywhere within the United States a federal offense, requires federal agencies to use their existing authorities to conserve listed species, prohibits federal agencies from taking actions that may jeopardize a species’ existence, provides a formal structure for listing endangered species, and provides a means for citizens to bring suit against any federal agency for failure to meet its obligations under the Act (Flather et al., 1994). Ayensu and DeFilipps (1978) noted that a species may be rare at the edge of its range, but not endangered or threatened as a whole. In determining national endangered, threatened, and extinction status, the total range and abundance of the species must be considered. However, states may further protect a species threatened with extirpation. Still, the cost of protecting individual species and habitats against multiple stresses is high, and the reality is that enforcement on public and private lands is generally weak.

VII. SELECTED EXAMPLES OF ENDANGERED PLANTS

Coleus forskohlii (Willdenow)

Coleus forskohlii, a 40-cm-tall, rare herb, is found in the Yunnan Province of China, Bhutan, India, Nepal, Sri Lanka, and Africa at about 2300 m on steep slopes (Fig. 3). Compounds extracted from the roots have long been a Hindu and Ayurvedic traditional medicine. Rampant collection has increased the rarity of this species. A German pharmaceutical company holds at least six U.S. patents for use of the plant as treatments for high blood pressure, cardiovascular disease, colic, respiratory problems, insomnia, painful urination, and convulsions. This is sometimes referred to as “biopiracy,” when the intellectual property of indigenous peoples is appropriated and used by foreign companies to develop and patent commercial products.

Fitzroya cupressoides

Fitzroya cupressoides is an ancient tree species in southern Chile (Fig. 4). Only 9% of the world’s temperate...
forests are in the Southern Hemisphere, and one-third of the threatened temperate forests occur in Chile. The highest biodiversity in any temperate forest is also found in Chile. These forests are remarkably productive, with some of the world’s largest concentrations of biomass. Old-growth Fitzroya cupressoides trees often reach 4 to 5 m in diameter and may live for 6000 years. One-third of Chile’s forests were burned or cleared by 1955. Some Fitzroya populations are protected in nature reserves, but most of the forests containing this species are privately owned.

*Sarracenia rubra* ssp. *alabamensis*

The Alabama canebrake pitcher-plant is a carnivorous plant with maroon flowers on 0.6-m stalks originating from rhizomes (underground roots; Fig. 5). It is found in sandy and gravelly bogs, seeps, springs, and swamps, and flowers from late April to early June. *Sarracenia rubra* ssp. *alabamensis* is restricted to only 12 localized sites in a three-county area in central Alabama. Four of the 12 sites have 70 to 300 plants each, and half the populations have 2 to 20 plants each. Much of the original habitat (16 other sites) has been modified or destroyed by agriculture and construction of farm ponds in boggy areas. Fire exclusion, gravel mining, and invasive plants pose additional threats. Several populations have also been lost or degraded by plant collectors.

*Encephalartos longifolius*

South African cycads are ancient gymnosperms and the most primitive living seed-bearing plants on Earth (Fig. 6). They flourished 50 to 60 million years ago and provided forage for dinosaurs before then. In South Africa, all 40 cycad species are endangered, and some species are extinct in the wild. The thick-trunked plants
with rigid spiked leaves grow very slowly; some species take 100 years to grow 1 m. Habitat loss and competition from invasive exotic plant species are often cited as causes of rarity, but illegal collecting is also a major problem. South Africa has some of the world’s strictest laws controlling cycad theft, but the thefts continue. Some cycads now have implanted microchips for identification and tracking purposes in an effort to curb poaching.

_Pterostylis truncata_

Brittle greenwood is a ground-dwelling orchid that emerges in the fall with large, squat flowers (Fig. 7). It is a clonal plant that can regenerate vegetatively, and its flowers can be pollinated by a small flies. _Pterostylis truncata_ is found in only three locations in south-central New South Wales, Australia. One of the populations is threatened by introduced European rabbits (_Oryctolagus cuniculus_), feral goats (_Capra hircus_), and eastern gray kangaroos (_Macropus giganteus_). An additional recent threat comes from the highly invasive weed _Chrysanthemoides monilifera_. The second population is on private land, where it is potentially threatened by kangaroos and rabbits. The third population occurs in a forest reserve; here it is threatened from trampling by orchid enthusiasts, weed invasions, and bird predation.

**VIII. IMPLICATIONS**

Reducing the rate of habitat loss around the world will be difficult. Between 1980 and 1990, species-rich tropi-
cal forests were cleared at the rate of 6.3 million ha/yr (15.4 million acres/yr), or 0.8% of the forest per year (Heywood, 1995). Deforestation causes habitat loss, habitat fragmentation, and edge effects at the boundaries, so the effects are greater than indicated by the actual deforested area. Large areas will be lost to urbanization and agriculture. Many dry grasslands in Germany have been converted to range and arable land in recent decades, making it more difficult to protect the nation’s 164 threatened plant species (Heywood, 1995). Thus, saving critical habitats throughout the world is seen as increasingly important and extremely urgent.

A species-by-species approach to rare plant conservation is expensive and difficult. However, the unstated assumption of the habitat preservation approach is that species are inseparably linked to habitats, which in turn are stable and predictable. Yet because habitats may be neither stable nor predictable (Flather et al., 1994),...
both species and habitats must be monitored to protect endangered plants and animals. In Australia, management techniques to protect critical habitats and species include: burning or slashing overgrown vegetation, removal of weeds, removal of grazing animals, hand pollination of selected species, propagation and seed storage, reintroduction into restored habitats, and quarantine to reduce the threat of introduced pathogens (Cropper, 1993).

Less than 10% of named plant species have been analyzed for medicinal or nutritional properties (Stermer, 1995). Nonetheless, 25 to 40% of all drug prescriptions in the United States contain plant ingredients (Durant and Saito, 1985), and many of these ingredients cannot be synthetically made. About 80% of people in developing countries use traditional medicines. As more and more plant species go extinct, so may our chances to find the next heart medicine (e.g., *Digitalis*; foxglove) or treatment for childhood leukemia (from *Catharanthus roseus*; the rosy periwinkle).

To improve the effectiveness of biodiversity conservation, increased emphasis is needed on systematic surveys and monitoring. Many species may be classified as rare owing to poor surveys, as evidenced by the rate of species discoveries. Since 1970, for example, one botanist has discovered 55 new plant species in Utah, and over 80 species have been named since 1970 (Durant and Saito, 1985). Botanists searching the well-studied Rocky Mountain National Park in Colorado added over 100 species to the Park’s plant checklist between 1987 and 1992 (Stohlgren et al., 1997). On average, one or two native plant species are added to the flora of New York each year. The Nature Conservancy and Natural Heritage Programs have found that plant surveys often show that many plant species are more common than previously believed. For example, several populations of rare orchids have been found in Australia after intensive searches. Systematic surveys of plants and rare habitats are badly needed.

The preservation of intact ecosystems may be the most promising way to protect endangered plants. It is now widely understood that maintaining natural disturbance regimes, such as fire and flooding, is important for many rare species (Cropper, 1993), and that preserv-
ing the habitat around rare plant locations is vitally important. However, subtle assaults to endangered species may include the use of fertilizers, herbicides, and insecticides that may reduce plant pollinators, invasive plant species that may out-compete the endangered plants, and introduced foreign diseases, insects, or domesticated/feral animals that may further endanger plants. Where habitat loss and degradation have been significant, habitat restoration efforts and species reintroductions are needed.

Cultivation, the last resort for endangered plants, may become necessary in some cases to preserve genetic variation. Franklinia (Franklinia alatamaha) is a familiar example. Franklinia is a small tree that was restricted naturally to the Altamaha River basin in southeastern Georgia. Now extirpated in the wild, the species survives as an ornamental throughout the eastern United States. In Australia, 1053 of 3329 rare and threatened plant species are found only in botanical gardens, and 515 plant species are held in only one collection (Cropp, 1993). Several botanical gardens in the United States have active programs to study, collect, and grow rare and endangered plants from all over the world. However, duplicate and more complete collections are needed in most countries, and such a system of collections should not be viewed as a substitute for preserving native habitats and ecosystems.

Some plants have appeared to bounce back from extinction. Mountain golden heather (Hudsonia montana) was described by Thomas Nuttall in 1818 in North Carolina, and was thought to be extinct in the 1960’s. About 2000 individuals were found in the Blue Ridge Mountains around 1990 (Burton, 1991). Running buffalo clover (Trifolium stoloniferum) was also believed to be extinct, but it was rediscovered in 1983 in West Virginia and later discovered in four other states. Also in 1983, Lomatium peckianum was rediscovered in Oregon after “disappearing” for over 50 years. In 1985, one species of clover (Trifolium microcephalum) that had not been seen since the Lewis and Clark expedition in 1805–1806 was rediscovered. Such stories are not uncommon. Eleven plant species in New York have been “rediscovered” in the past 10 years. However, expecting miraculous rediscoveries for many long-lost species is probably unrealistic.

This article has focused on endangered vascular plants. However, many non-vascular plants are similarly threatened. For example, >50% of the mushrooms in Europe are listed as endangered or threatened in at least one country. Species that were once common,
such as Hydnum repandum, have been extirpated in some countries. Over-collection of the lichen Gymnoderma lineare in the Great Smoky Mountains National Park has led to its recommendation for listing. Air pollution and acid deposition are known to adversely affect many non-vascular plant species. The assessment of endangered plants cannot be done without assessing the interacting species (e.g., pollinators and symbiotic fungi) and the ecological processes that affect complexes of rare and common species.

Understanding the causes and consequences of rarity also requires a comprehensive knowledge of biology, evolutionary and recent history, and species demography. Often, the causes of population decline may be elusive. For example, Torreyra taxifolia, the Florida torreyra, is a narrowly restricted endemic conifer that has suffered catastrophic declines since the 1930s. Pathologists and ecologists have studied the problem relentlessly and found no obvious cause for the decline. There are now fewer than 1500 trees in the wild, with no solonion in sight. In many cases, careful field and laboratory experiments may be necessary to isolate the causes of rarity.

It is equally important to increase public awareness about the ecology of rarity and the economic and social consequences of losing our endangered plants. In the end, protecting endangered species and biodiversity is a question of ethics and values. Endangered plants are best viewed as valuable resources and inherently valuable species with which we share the Earth.

I. Reptiles and Amphibians
II. The Conservation Status of Reptiles and Amphibians
III. Threats to Reptiles and Amphibians
IV. Declining Amphibian Populations

GLOSSARY

amphibian Member of a class of vertebrates (the Amphibia), comprising frogs and toads (order Anura), newts and salamanders (order Caudata), and caecilians (order Gymnophiona), which typically return to water to breed and pass through an aquatic larval stage with gills. Amphibians have a moist skin without scales, which is permeable to water and gases.

reptile Member of a class of vertebrates (the Reptilia), comprising turtles and tortoises (order Testudinata), lizards, snakes, and worm-lizards (order Squamata), the tuatara (order Rhynchocephalia), and crocodiles and alligators (order Crocodylia), which typically lay eggs with a leathery, impermeable shell. Reptiles have a dry, horny skin with scales, plates, or scutes.

THE EARTH CURRENTLY CONTAINS approximately 7150 species of reptiles and 4600 species of amphibians. These data are underestimates because new species are still being discovered, partly as a result of exploration of previously unknown parts of the world and partly because new genetic techniques have revealed that what were thought to be single species are in fact several species. Many reptile and amphibian species are currently listed as threatened or endangered, and several have recently become extinct. Current estimates of the number of species at risk of extinction do not reflect the true extent of the threat faced by these two groups. Both groups are threatened by a variety of environmental factors.

I. REPTILES AND AMPHIBIANS

The reptiles and amphibians are two groups of vertebrate animals that are commonly grouped together, and the study of the two groups is called herpetology. In reality, however, the biological differences between reptiles and amphibians are more numerous and extensive than are their similarities. Amphibians are descended from fishes and, like fishes, both amphibians and reptiles are ectothermic, meaning that the heat that they require to maintain physiological processes is derived externally, directly or indirectly from the sun. Reptiles are the ancestors of the birds and the mammals, which are both endothermic, meaning that body heat is primarily generated within their bodies. Their dependence on external heat sources limits both amphibians and reptiles to tropical and temperate regions of the earth and both groups are especially numerous in the tropics;
80% of the world’s amphibian and reptile species live in tropical habitats. There are two major differences between amphibians and reptiles. First, amphibians have a thin, permeable skin that severely limits their ability to retain water within the body. In contrast, reptiles are covered in impermeable scales and are able to retain water very effectively. Second, the eggs of amphibians are bound by only a thin membrane and can only survive if they are kept wet. The eggs of reptiles are covered by a hard shell, providing a sealed environment for the developing embryo, which does not depend on external sources of water. These two differences mean that, whereas reptiles have successfully colonized very dry habitats, including deserts, amphibians are restricted to those habitats in which water is available for all or most of the year.

Neither reptiles nor amphibians are as well-known, in terms of documentation of species, as either the birds or the mammals. Neither group has been studied as intensively as birds and mammals, both are rather secretive in their habits, and both are very numerous in parts of the world, notably tropical forests, that have not been fully explored. Therefore, new species of amphibians and reptiles are being discovered and described at a much higher rate than is the case for birds or mammals. The number of recognized species of amphibians is approximately 4600 and of reptiles approximately 7150, but both these figures are continuously being revised upwards as new species are described.

There are three major groups of amphibians: the frogs and toads (approximately 4500 species), the salamanders and newts (approximately 415 species), and the caecilians (approximately 165 species). Reptiles are divided into four major groups: the lizards, snakes, and worm-lizards (approximately 6850 species); the turtles and tortoises (approximately 2200 species); the alligators and crocodiles (approximately 22 species); and the tuataras (1 species).

II. THE CONSERVATION STATUS OF REPTILES AND AMPHIBIANS

An accurate estimate of the number of reptile and amphibian species that are currently threatened with extinction, or which have recently become extinct, is not currently available. Table I presents two recent estimates of the numbers of endangered and threatened reptiles and amphibians. The disparity between the two sets of data, and in the total numbers of species that they each assume, reflects the current incompleteness of our knowledge of these two groups and of their conservation status. Currently, major efforts are being made, for example, by the Species Survival Commission of the International Union for the Conservation of Nature (IUCN), to correct this situation by compiling accurate lists of reptile and amphibian species and making assessments of their current status.

III. THREATS TO REPTILES AND AMPHIBIANS

Many environmental factors have been identified that are detrimental to the continued survival of reptile and amphibian species. Some of these are common to the two groups of animals; others are more relevant to one group than the other.

A. Habitat Destruction

The single most important factor that adversely affects reptiles and amphibians is habitat destruction and modification. Many habitats that are essential for the two groups are shrinking or disappearing at an accelerating rate as a result of human population growth and economic development. Tropical forests provide some of the most species-rich habitats in the world and are particularly vulnerable to destruction by humans, with the land being turned over to agriculture or to provide residential areas for people. In 1991, the United Nations Food and Agriculture Organization reported that the world’s tropical forests were being destroyed at a rate that was 50% faster than a decade previously. Tropical forests support a high diversity of reptile and amphibian species, many of them still to be described. At the current rate of deforestation, within 30 years all extensive areas of tropical forest, together with their reptile and amphibian fauna, will have disappeared.

Amphibians are particularly dependent on freshwater habitats, especially for breeding. The World Wildlife Fund (1998) published a report which suggests that freshwater habitats are the most seriously threatened on Earth. Between 1970 and 1995, the diversity of freshwater species decreased by 50%, a faster rate of decline than has been detected in any other component of the global ecosystem. Although there is legal protection for some of the world’s larger lakes and rivers, or at least parts of them, largely because of their importance in providing fish to support the human population, the smaller streams, ponds, and swamps that are essential habitat for amphibians are generally not protected. The draining of wetlands to make way for agriculture and housing has had a particularly serious negative effect on many amphibian populations.

In much of western Europe, traditional methods of agriculture previously provided good habitat for amphibians in the form of small woodlands, hedgerows, and numerous ponds created to water livestock. In the past 30 years, however, agricultural practices have changed and all these landscape features have been destroyed over very large areas. In parts of Britain, for example, the number of ponds suitable for amphibians to breed in has declined by 90% in the past 50 years. Habitat destruction in a given area is not always total; often, small pockets of forest, heathland, or wetland are set aside for conservation purposes. This results in the fragmentation of previous areas of habitat and there is increasing evidence that habitat fragmentation is a serious threat to the continued survival of species that it was assumed were afforded some degree of protection. Fragmentation of habitat leads to the isolation of small populations of reptile or amphibian species. Inbreeding in such populations reduces their genetic diversity, and their isolation prevents interchange of individuals and thus of genetic variation with other populations. As a result, isolated populations tend to decline slowly and eventually die out, even though they are protected. Many reptiles and amphibians have only limited powers of dispersal, and even a road built through an area of otherwise suitable habitat will reduce dispersal.

B. Climate Change

There is increasing evidence that the earth’s climate is undergoing major changes as a result of human activities such as the destruction of forests. Most notably, average temperatures are steadily increasing in many parts of the world and there are major, long-term changes in rainfall patterns. The long-term effects of such changes on reptiles and amphibians are largely a matter of speculation, but there is evidence that they have had an impact on some species. For reptiles, temperature is crucial because many species rely on basking in the sun to raise their body temperature to a level at which they can carry out essential activities such as feeding and reproduction. For amphibians, rainfall patterns are critical because they determine whether, and for how long, the small streams and ponds in which they breed contain water.

The apparent extinction of the golden toad (Bufo periglenes), along with several other frog species, in the montane forest of Costa Rica appears to be due, at least in part, to climate change (Pounds et al., 1999). A critical factor in the habitat of this species is low-lying cloud, which provides the water that maintains water flow in the small streams in which many of the native frogs breed. The extent of such cloud has decreased in recent years, leading to extensive reductions in the amount of available water and thus a general reduction in stream habitat. In Britain, winters are becoming increasingly less severe and there is evidence that several
native amphibians are now breeding earlier in the spring than they were 20 years ago.

C. Ultraviolet Radiation
The steady erosion of the ozone layer in the earth's stratosphere has led to an increase in the amount of ultraviolet (UV) radiation reaching the earth's surface. Such radiation, especially UV-B, is harmful to living organisms and there is accumulating evidence that it may be a factor in the decline of some amphibian species, especially those living at high altitudes, where incident levels of UV-B are highest. Increased UV-B causes the genetic material DNA to mutate, leading to the abnormal development and eventual death of embryos. Frog and toad species that lay their eggs close to the surface of water, which filters out UV-B, may be particularly susceptible to increased UV-B. Although there is considerable experimental evidence that ambient levels of UV-B radiation are harmful to the early life stages of amphibians (Blaxter et al., 1993), it is not clear to what extent elevated UV-B has been a factor in the decline of amphibian populations in nature (Alford and Richards, 1999).

Amphibian species vary in their susceptibility to elevated UV-B. Some species, such as the Pacific tree frog (Hyla regilla), produce high levels of the enzyme photolyase, which repairs DNA damage of the kind caused by UV-B. This species is one of those that has not declined in the Pacific Northwest of North America, unlike species with lower photolyase levels, such as the Cascades frog (Rana cascadensis) and the western toad (Bufo boreas) (Blaxter et al., 1994). If elevated UV-B does affect natural populations of amphibians, it is likely that it acts synergistically with other adverse environmental factors, such as acidification and pathogens. There is experimental evidence that both these factors have a more detrimental effect on the survival of amphibian embryos when they are combined with elevated UV-B.

D. Pollution
Environmental pollution has caused the decline or extinction of some local populations of amphibians, and it is likely that it also has a widespread harmful effect. For example, declines of amphibians in Yosemite National Park in California appear to be due to chemical pollution that has drifted on the wind from agricultural areas many miles away. Amphibians may provide sensitive biological indicators of pollution because their highly permeable skin rapidly absorbs toxic substances.

Examples of pollutants include fertilizers, herbicides, pesticides, heavy metals, and poisoning resulting from logging and mining operations. A major form of pollution that can affect very large areas is atmospheric acid deposition or acid rain. Much of the rain that falls in regions downwind from major industrial areas, such as in the eastern United States, Scandinavia, and western Europe, is markedly acidic, with a pH of approximately 4.3; unpolluted rain has a pH of approximately 5.6. Acid rain lowers the pH of natural water bodies below the tolerance level of many species of amphibians. The toxic effects of low pH on amphibian development are well-documented. Acidic conditions reduce the mobility of sperm and may cause them to disintegrate, with a consequent reduction in the fertilization success of eggs. Eggs that are fertilized may develop abnormally, if they hatch, they produce deformed tadpoles that soon die. Acid precipitation has been implicated in the declines of tiger salamanders (Ambystoma tigrinum) in the Rocky Mountains of Colorado and of the natterjack toad (Bufo calamita) in lowland heaths in Britain.

Pollution in the form of solid plastic waste is harmful to some sea turtles that may eat it. Green turtles (Chelonia mydas) eat plastic bags while feeding on aquatic plant food and leatherback turtles (Dermochelys coriacea) mistake plastic bags for their jellyfish prey. Half of the sea turtles examined in some localities have plastic debris in their intestines. This may interfere with their digestion, respiration, and buoyancy, and some plastics are toxic.

Some chemical compounds of human origin are readily absorbed by animals and interfere with their endocrine systems; these are known as endocrine disrupters and include estrogen mimics, which are compounds that disrupt the reproductive development of both sexes (Stebbins and Cohen, 1995). Males may become feminized to varying degrees, for example, suffering lowered sperm counts. Reptiles are especially susceptible to such effects because of their sex-determination mechanisms which, in many species, are very dependent on environmental factors. Of particular concern are polychlorinated biphenyls (PCBs), industrial chemicals such as those used in fire retardants and adhesives, which persist for a very long time and accumulate in the environment. Some PCBs have a molecular structure so similar to estrogen that they mimic its effects when they enter an animal's body. PCBs can turn male red-eared slider turtles (Trachemys scripta) into females, drastically reducing the reproductive success of populations.

Many pesticides, such as DDT, are not only poison-
During the 1990s, mass mortalities occurred among amphibians in many parts of the world have occurred, and some of these have had a major impact on the populations of many species. These were caused by ranaviruses similar to pathogens that have caused mass mortalities among tiger salamanders (Ambystoma tigrinum) at several localities in the United States and Canada during the past 5 years (Daszak et al., 1999). Recently, a disease called chytridiomycosis has been identified in Australia and Central America, where it has wiped out many populations of frogs, and among captive amphibians in the United States (Daszak et al., 1999). The disease is caused by a chytrid fungus, which is an organism that invades the skin of amphibians. Whether it kills them by blocking water and oxygen transport across the skin or by producing a lethal toxin is not known. These sudden, major outbreaks of the same, previously unknown disease in widely distant parts of the world raises several questions that are urgently being addressed: Is the chytrid fungus a new organism that has just evolved? Is it a long-established organism that has recently found its way to these localities and, if so, how? One possibility is that the fungus is not new and has long been distributed worldwide, and that what has changed is the susceptibility of amphibians to it. It has been suggested that, as a result of one or more kinds of environmental stress, the immune system of amphibians has been compromised so that they are no longer able to survive infection by the fungus.

Another kind of pollution which may affect amphibians in agricultural habitats results from nitrates derived from fertilizers. Recent research has shown that frog tadpoles reared in water containing nitrates at levels low enough to be considered safe for human consumption suffered physical abnormalities, paralysis, and death (Macne and Blaustein, 1999). Nitrate fertilizers are widely used throughout the world and may constitute a serious threat to many amphibian populations.

### E. Disease

Diseases are a natural cause of morbidity and mortality among animals, but very little is known about their role as a determinant of population size among reptiles and amphibians. In the past few years, however, major outbreaks of disease among amphibians in many parts of the world have occurred, and some of these have had a major impact on the populations of many species. During the 1990s, mass mortalities occurred among populations of the common frog (Rana temporaria) in southeast Britain. These were caused by ranaviruses similar to pathogens that have caused mass mortalities among tiger salamanders (Ambystoma tigrinum) at several localities in the United States and Canada during the past 5 years (Daszak et al., 1999). Recently, a disease called chytridiomycosis has been identified in Australia and Central America, where it has wiped out many populations of frogs, and among captive amphibians in the United States (Daszak et al., 1999). The disease is caused by a chytrid fungus, which is an organism that invades the skin of amphibians. Whether it kills them by blocking water and oxygen transport across the skin or by producing a lethal toxin is not known. These sudden, major outbreaks of the same, previously unknown disease in widely distant parts of the world raises several questions that are urgently being addressed: Is the chytrid fungus a new organism that has just evolved? Is it a long-established organism that has recently found its way to these localities and, if so, how? One possibility is that the fungus is not new and has long been distributed worldwide, and that what has changed is the susceptibility of amphibians to it. It has been suggested that, as a result of one or more kinds of environmental stress, the immune system of amphibians has been compromised so that they are no longer able to survive infection by the fungus.

Another kind of pollution which may affect amphibians in agricultural habitats results from nitrates derived from fertilizers. Recent research has shown that frog tadpoles reared in water containing nitrates at levels low enough to be considered safe for human consumption suffered physical abnormalities, paralysis, and death (Macne and Blaustein, 1999). Nitrate fertilizers are widely used throughout the world and may constitute a serious threat to many amphibian populations.

### F. Commercial Exploitation

Many people in many parts of the world have long eaten amphibians and reptiles because they are a good and readily available source of protein. Until recently, such exploitation rarely had a serious impact on natural populations because it was localized, seasonal, and of low intensity. Unfortunately, modern commercialization of amphibians and reptiles for the world’s luxury food market is generally done with little regard for the long-term protection of natural populations. Most of the frogs that are killed for human consumption are not a vital component of the diet of local people in the developing world but are a luxury item in the diet of people in developed countries.

The scale of trade in frog legs has long been substantial, but it is beginning to be controlled and reduced. In 1976, 2.5 million kg of frog legs was imported into the United States, mostly from India and Japan. In France, the annual consumption is estimated to be 3000 or 4000 tons, imported mostly from Bangladesh and Indonesia. Until recently, 200 million pairs of legs were exported annually from Asia to the United States, Europe, and Australia; however, since 1987, India has banned this trade because declines in natural frog populations had caused dramatic increases in the densities of insect pests.

There is also a substantial trade in reptile meat. Between 1979 and 1987, the hunting of alligators in Louisiana yielded 45,000 kg of alligator meat each year. Many turtles are heavily exploited as a food source, both by indigenous people and to supply luxury food markets in developed countries. The green iguana (Iguana iguana) has declined severely as the result of being hunted for food. Eaten by humans in Central America for centuries, destruction of its habitat and the expansion of the human population have led to it being hunted much more intensely in the past 30 years. In the late 1960s, as many as 150,000 iguanas were eaten each year in Nicaragua alone. Not only is iguana flesh regarded as a great delicacy but also their fat and their eggs are used for a variety of medicinal purposes, including a cure for impotence.

The highly durable skin of reptiles makes it an excellent alternative to leather, and reptile skins have long been used...
have considerable potential as medicines. For example, list of compounds, found in the skin of frogs, that their continued existence or ensure their survival, declarations is doubtful, but the future exploitation of amphibians and reptiles could either seriously threaten relations with them, deliberately or accidentally, a variety of organisms that have been harmful to indigenous wildlife. Populations of many reptile species that are endemic to islands have been devastated by the introduction of alien rats, cats, dogs, and other animals that feed on them or their eggs, and introduced pigs and goats have destroyed the ground cover that supports their food supply and which they need to escape from predators. The tuataras (Sphenodon) have become extinct on the two major islands and on many of the smaller islands of New Zealand and are now confined to a very few small islands that remain free of alien immigrants. Introduced rats have caused the extinction of several frog species of the genus Leiopelma on New Zealand; only three such species still exist, reduced to very small populations on remote, rat-free islands.

The eggs and larvae of amphibians make easy prey for fishes and other freshwater predators, and many amphibian species are dependent on water bodies that are free of fish to breed successfully. In many parts of the world, exotic fishes have been introduced by humans to the detriment of native amphibians. In California, trout have been introduced, to provide sport fishing, to high-altitude lakes and have caused the decline of several amphibian species; in many parts of the world, mosquito fish (Gambusia affinis) have been introduced to control mosquitoes and other insect pests, with equally disastrous results for native amphibians.

Some reptiles and amphibians have been implicated in the declines of other species where they have been introduced to parts of the world in which they did not previously occur. The most notable example is the marine toad (Bufo marinus), a native of Central America, which was deliberately introduced to Hawaii, Australia, and many other places to control insect pests in sugar-cane plantations. In Australia, where it is known as the cane toad, it has spread relentlessly outwards from the Queensland coast to the detriment of much of Australia’s native fauna, including many frog species. The American bullfrog (Rana catesbeiana), a native of eastern North America, has been introduced to many parts of the world to be farmed to supply the trade in frog legs, and it has had a harmful effect on many native frog species both because it is a greatly superior competitor and because it is a predator of smaller frogs. Brown tree snakes (Boiga irregularis), accidentally introduced onto the island of Guam, have seriously reduced or extirpated not only populations of endemic birds but also several native reptiles.

### G. Introduced Species

As the human population has expanded and people have colonized new parts of the world, they have taken with them, deliberately or accidentally, a variety of organisms that have been harmful to indigenous wildlife. Populations of many reptile species that are endemic to islands have been devastated by the introduction of alien rats, cats, dogs, and other animals that feed on them or their eggs, and introduced pigs and goats have destroyed the ground cover that supports their food supply and which they need to escape from predators. The tuataras (Sphenodon) have become extinct on the two major islands and on many of the smaller islands of New Zealand and are now confined to a very few small islands that remain free of alien immigrants. Introduced rats have caused the extinction of several frog species of the genus Leiopelma on New Zealand; only three such species still exist, reduced to very small populations on remote, rat-free islands.

The eggs and larvae of amphibians make easy prey for fishes and other freshwater predators, and many amphibian species are dependent on water bodies that are free of fish to breed successfully. In many parts of the world, exotic fishes have been introduced by humans to the detriment of native amphibians. In California, trout have been introduced, to provide sport fishing, to high-altitude lakes and have caused the decline of several amphibian species; in many parts of the world, mosquito fish (Gambusia affinis) have been introduced to control mosquitoes and other insect pests, with equally disastrous results for native amphibians.

Some reptiles and amphibians have been implicated in the declines of other species where they have been introduced to parts of the world in which they did not previously occur. The most notable example is the marine toad (Bufo marinus), a native of Central America, which was deliberately introduced to Hawaii, Australia, and many other places to control insect pests in sugar-cane plantations. In Australia, where it is known as the cane toad, it has spread relentlessly outwards from the Queensland coast to the detriment of much of Australia’s native fauna, including many frog species. The American bullfrog (Rana catesbeiana), a native of eastern North America, has been introduced to many parts of the world to be farmed to supply the trade in frog legs, and it has had a harmful effect on many native frog species both because it is a greatly superior competitor and because it is a predator of smaller frogs. Brown tree snakes (Boiga irregularis), accidentally introduced onto the island of Guam, have seriously reduced or extirpated not only populations of endemic birds but also several native reptiles.

### H. Species at High Risk of Extinction

The fact that introduced species, such as cane toads and the American bullfrog, can multiply and spread to the point at which they become a serious threat to other species indicates that population declines among amphibians are not due to a single factor that affects all species. Although many species are adversely affected by current environmental conditions, at least some can thrive. This raises the question of whether there are particular characteristics of certain reptiles and amphibians that make them particularly susceptible to environmental changes.

There are many reptile and amphibian species, notably many turtles, that live for a long time but have
delayed sexual maturity and low fecundity. Such life history characteristics limit the capacity of a population that has been reduced, for example, by human exploitation, to build up its numbers. Some species have very low reproductive rates because they do not breed every year. This is a feature of many amphibian species that live in near-desert habitats in which sufficient rain to fill their breeding ponds falls only occasionally.

Many amphibians move only small distances during the course of their lives. Such species have very poor dispersal abilities, with the result that, if their habitat is destroyed or modified, they do not have the option of colonizing suitable habitat elsewhere. There are many species that have very specialized habitat requirements and very restricted distributions. Such species are vulnerable to any very small change in their environment. Examples of such species are the golden toad (B. periglenes) of Costa Rica and two species of gastric-brooding frog (Rheobatrachus), restricted to a very few streams in southeast Queensland, Australia. All three species appear to have become extinct in the past 10 years.

Animals of all kinds that live on small oceanic islands are especially vulnerable to extinction, and reptiles and amphibians are no exception. Island species are often very vulnerable to introduced predators, such as cats, rats, dogs, and mongooses, having evolved in an environment in which such predators were previously absent. Small islands are also highly susceptible to habitat destruction and excessive hunting. Among endangered reptiles that live on islands are giant tortoises such as those found on Aldabra and the Galapagos.

Some reptiles and amphibians are vulnerable to exploitation by humans and to natural predation because they gather to breed in large numbers. A marine turtle, Kemp's ridley (Lepidochelys kempi), was reduced to near extinction in the 1950s by the commercial exploitation of breeding females and eggs, gathered at their coastal breeding sites in Mexico and Texas. This species is now internationally protected and its numbers are recovering.

Migratory species, such as some sea turtles, are very vulnerable both because their conservation requires that they be protected in two, often distant, parts of the world and because they have to make long journeys across possibly hazardous environments. The green turtle (Chelonia mydas) is protected in Australia but is exploited in Indonesia. Many amphibians migrate to specific breeding sites that are used year after year. High mortality can occur when these sites are near roads. In some places in the United States and Canada, roads that cross frog or salamander migration paths are closed in the spring, and in several places in Europe special tunnels have been built to allow frogs and toads to pass safely under roads.

In the Monteverde cloud forest reserve in Costa Rica, the formation of large mating aggregations of the spectacularly colorful golden toad (B. periglenes) used to be an annual event. In 1989, however, this species failed to appear and it has not been seen since (Pounds and Crump, 1994). The golden toad has become the icon of the declining amphibian phenomenon, but it is only one of many species throughout the world that have disappeared because of this deeply disturbing process. The Monteverde reserve was established to protect biodiversity and yet, since 1990, 40% of its native frog and toad species have disappeared (Pounds et al., 1997). Similar catastrophic declines of amphibian populations in supposedly pristine, protected habitats have occurred in Queensland, Australia, the Atlantic forests of Brazil, and the Pacific Northwest of North America. In a section of California's Sierra Nevada that includes Yosemite National Park, 5 of 7 amphibian species have seriously declined in recent years. In protected remnants of tropical rain forest in eastern Queensland, 14 species of stream-dwelling frogs have drastically declined or totally disappeared. These events carry a disturbing message for conservationists: As one scientist said at a recent workshop on amphibian declines, “locking up nature just isn’t working.”

Although it is clear that the majority of the world's amphibians that have declined or become extinct in the past 50 years have done so as a result of habitat change or destruction, these declines in protected areas suggest that some other kind of process is adversely affecting amphibian populations. Because of their dual life history, spent partly in water and partly on land, and because none of their life stages (egg, larva, or adult) have the kind of protective covering possessed by animals such as insects, reptiles, birds, and mammals, it has been argued that amphibians are especially sensitive to environmental insults such as chemical pollution (Stebbins and Cohen, 1995). According to this argument, amphibian declines may be the prelude to an environmental catastrophe that could affect many forms of life. Like the coal miner’s canary, frogs may be providing an early warning to all biodiversity.

It is becoming increasingly clear that this kind of argument is not applicable to all amphibians. Indeed,
a feature of all the declines that have occurred recently in supposedly protected habitats, such as Monteverde, is that although some species have declined or vanished, others have been quite unaffected. It is not clear, however, what character or characters differentiate amphibian species that have declined in pristine areas from those that have not. Amphibians are a very diverse group of animals in terms of their habits, their life histories, and their physiology. For example, although some species do have a highly permeable skin and are extremely sensitive to pollutants, for others the skin is highly effective as a protective covering. The American bullfrog (R. catesbeiana), for example, seems to be remarkably resistant to the effects of pesticides.

The current intense interest in amphibian population declines began in 1989 at the first World Congress of Herpetology. In 1991, the Declining Amphibian Populations Task Force (DAPTF) was set up under the aegis of the Species Survival Commission of IUCN, and by 1993 more than 500 populations of amphibians on five continents had been listed as declining or of serious conservation concern (Vial and Saylor, 1993). The DAPTF is continuing its work and plans to publish major overviews of the current status of amphibians throughout the world in 2001. Currently, it is clear from the information already gathered by the DAPTF that (i) amphibian population declines are widespread throughout the world and (ii) that they are not due to a single, global cause. Rather, they are the result of many factors, with more than one factor usually being implicated in any particular instance.

A. A Possible Link with Deformities?

Since a group of children found some severely deformed frogs in Minnesota in 1991, there has been much media attention devoted to this phenomenon in the United States, often making a link with amphibian declines there and elsewhere. These deformities reflect abnormalities in development and include missing eyes, digits, or entire limbs as well as extra limbs, sometimes growing from unexpected parts of the body. There are several reasons for being cautious about a possible link between deformities and the global decline phenomenon, however. First, such deformities are not new but rather have been reported periodically for more than 200 years, especially in the mid-northern United States. Second, although reports have become more frequent recently, there is no reason to believe that deformed frogs have become more common; there are simply more people looking for them. Third, developmental abnormalities are caused by a variety of natural causes, including parasites and injury following attack by predators, and by anthropogenic factors, such as chemical pollution and increased UV-B radiation.

Deformed amphibians are a cause for concern because they are often symptomatic of local environmental degradation. Before we can conclude anything of wider significance from them, however, we have to remember that they are both naturally occurring and typical of amphibians and that they do not represent a new phenomenon. Only additional research into the role of various pollutants and of UV-B into the development of deformities can reveal to what extent they are another facet of processes that are adversely affecting amphibians on a global scale.

GLOSSARY

alien invertebrates Invertebrates intentionally or accidentally imported by humans into new geographic areas.

coevolution Long-term evolutionary adaptation of species to each other (e.g., mutually beneficial relationships between bees and flowering plants).

endangered species Species that are likely to become extinct in the near future because of normal human activities. Examples of such activities are land clearing for agriculture or housing and accidental importation of invasive species through commerce.

endemic species Species confined to areas where they evolved (e.g., flightless crickets in the Hawaiian Islands).

habitat specialists Species found only in a specific habitat (e.g., species found only in forests of Sequoia trees).

terrestrial animals Animals that live on land for their entire lives (e.g., spiders) as opposed to animals that live in water for their entire lives (e.g., lobsters). There are also many amphibious animals that spend part of their lives in both places (e.g., dragonflies).

terrestrial invertebrates Animals that are not vertebrates (such as fish, reptiles, amphibians, birds, and mammals) that live on land for their entire lives. Examples are all insects except for those with aquatic larvae; nonaquatic mites and nematodes; and all spiders, millipedes, centipedes, and scorpions.

SIMPLE STATEMENTS CAN RAISE the most complicated questions. There are two simple facts about endangered terrestrial invertebrates. The first is that there are great numbers of these endangered animals—many thousands of species. The second is that nobody knows enough to make a comprehensive list of these species. Without such a list, how is it possible to say whether this list would be long or short and whether it would really contain many thousands of species? What is the evidence that there are huge numbers of endangered terrestrial invertebrates that are missing from lists of endangered species? Why aren’t biologists moving more quickly to add the missing names to the list? Are terrestrial invertebrates particularly vulnerable to ongoing rapid changes caused by our own species? If there are such large numbers, what does this mean for the forests, fields, deserts, and other habitats that are threatened...
with the loss of these species? What does it mean for our own species?

I. EVIDENCE OF MULTITUDES OF ENDANGERED TERRESTRIAL INVERTEBRATES

The belief that there are very large numbers of endangered terrestrial invertebrates is based on a combination of knowledge and logic. The great majority of all animals are terrestrial invertebrates, in which are included at least three-fourths of the insects, most mites, terrestrial mollusks, a large percentage of the nematodes, and all the spiders, millipedes, and centipedes. The last three groups total more than all the vertebrates. If the factors that endanger other animals also affect terrestrial invertebrates, the number of endangered terrestrial invertebrates must be large indeed. These factors are primarily habitat destruction and the introduction of nonnative species into new areas, and it is known that they affect terrestrial invertebrates.

Hawaii, showcase of beleaguered biota, is a revealing example of these factors at work on terrestrial invertebrates. Of the total number of animals that live on the Hawaiian Islands and in the surrounding sea, about three-fourths are terrestrial invertebrates, 99% of which are found only on the Hawaiian Islands. The islands are so strongly affected by habitat destruction that whole habitat types, containing all their habitat-specific invertebrates, are considered endangered. Invasions of alien plants and animals are so severe that whole groups of invertebrates have been devastated, such as the Hawaiian land snails, which were originally believed to number approximately 1000 species but now number approximately 500, with most of the remaining species endangered. The Hawaiian Islands may provide the best opportunity to document relatively easily the scale of the threat to terrestrial invertebrates in especially vulnerable places, such as oceanic islands (Fig. 1).

A. Logistical Problems

A major logistical problem is an insufficiency of experts. There are so many species of terrestrial invertebrates that it is easy to find groups with hundreds or thousands of species that can only be identified by two or three people. Who can identify the dark-winged fungus gnats, Indonesian bark beetles, the egg parasites of tropical sac spiders, the mites associated with millipedes, or any one of innumerable large groups of small organisms? The few people who do study these groups are generally overwhelmed with species that are undescribed and with species whose biology is almost completely unknown. Recognizing any of these species as endangered requires documentation of distribution and abundance—levels of information that will probably not be available for most terrestrial invertebrates for approximately another century (Fig. 2).

A second logistical problem is that specialized knowledge is needed not only for identifying most terrestrial invertebrates but also for finding and counting them. Species that are rare in museum collections are not necessarily rare in nature; they are frequently species that are difficult to find because their habits are unknown. Certain flightless pygmy mole crickets, for example, are very common in ancient dune areas in Florida, but until recently there were no specimens in museums because nobody knew to look for these insects just under the surface of the sand just after a heavy rain. Many grasshoppers have species-specific songs which biologists must learn to study the abundance of the
FIGURE 2 With regard to terrestrial invertebrates, there may be few people with the specialized knowledge to identify even large and easily characterized species. Many species could become rare or extinct without triggering alarms. The giant lacewing, Polystoechotes punctatus, apparently a common and widespread insect a century ago, is now so rare that few entomologists have seen a living individual. Nobody is writing distraught letters asking about the disappearance of this animal, and it does not appear on any list of endangered species. Nobody is doing any methodical surveys for this species; nobody knows how one would go about making such a survey because the ecology of the insect is poorly known. This species, which is relatively large (7-cm wingspread), distinctive, and of special interest because it is so primitive, has gone unrecognized as an endangered species. The great number of smaller and less conspicuous invertebrate species have that have become rare or extinct have even less of a chance of attracting attention.

Given all these logistical problems, however, there are still ways of quickly identifying large numbers of genuinely endangered invertebrates. There are whole groups of invertebrates that include many habitat specialists and have poor dispersal abilities, and therefore they are likely to be endangered if their habitat is reduced to small fragments. Examples of these unfortunate animals are the land snails, millipedes, flightless beetles, flightless grasshoppers and crickets, and several groups of primitive flies. It would be relatively easy to compile a long list of endangered invertebrates by surveying any old and distinctive habitat that is rapidly disappearing. There are some ecological groups of invertebrates that tend to have specific, coevolved relationships with other organisms and are endangered by anything that threatens their host. Examples of these excessively specialized invertebrates are most leaf-mining and gall-making insects and mites, seed predator insects, insects and mites associated with plant genera that contain only one species, pollen feeders that visit one or a few species of flowers, and the fleas, lice, feather mites, and den inhabitants of vertebrates. Since most species of endangered plants and vertebrate animals are likely to have at least one host-specific invertebrate, it would be relatively easy to compile a long list of endangered invertebrates by studying the invertebrate adult insects; this has recently become a tool for studying endangered grasshoppers. Estimating the abundance of a species also requires specific knowledge of life cycles and population dynamics. Many terrestrial invertebrates have a dormant period in the egg or pupal stage, during which they are almost impossible to find. Invertebrates often produce large numbers of offspring per female, and the percentage of survival of these offspring may be strongly dependent on variable factors, such as weather or the population levels of certain predators. This means that populations may go through frequent fluctuations of abundance and rarity, neither of which may be good predictors of the long-term survival of a population (Fig. 3).

FIGURE 3 The red widow spider (Latrodectus bishopi) is rare in the sense that it has a very small geographic range (a few areas of the Florida peninsula) and a strict habitat requirement (Florida scrub). Within its remnant patches of habitat, the red widow is sometimes very common, whereas at other times it is extremely rare. This is probably due to predation by natural enemies such as spider wasps and egg sac parasites. If one took a single survey in an area, one might conclude that this species was endangered or not at all endangered, depending on the population level at the time of the survey. Is this species endangered? Nobody knows. It depends on whether there are factors that could wipe out populations when they are at their low point, since the habitat for the species is now in smaller patches that are farther apart.
associates of larger and better known endangered species.

In summary, there are currently insurmountable difficulties that prevent the recognition of more than a small percentage of the probable number of endangered terrestrial invertebrates. Even this small percentage of easily recognized species, however, is not receiving the intensive attention that one might expect, which suggests that there are additional problems with recognizing endangered invertebrates.

B. Strategic Considerations

There are two species of bird lice (Franciscoa thompsoni and Neopsitticonirmus emersoni) that live only on the threatened Philippine cockatoo. These are examples of endangered invertebrates that might go unrecognized for strategic reasons. First, lice have no general appeal, and to say that this particular parrot is infested with unique and interesting species of lice is most unlikely to further spur efforts to save the bird. Simultaneously, there seems to be no strategic need to recognize the endangered species of lice because their survival depends on that of their host, whose status is already recognized. In the long run, however, it is important to understand that each species of organism represents a complex of ecological relationships, and the presence of a host-specific parasite is indicative of ancient sequences of adaptation which add to the significance of the host species. Moreover, host animals may be molded by their parasites in ways that are just beginning to be acknowledged by biologists. Therefore, for example, mutual grooming behavior may have evolved through the presence of body parasites on places that are difficult to reach, and this mutual grooming may have a major role in social bonding between individuals. Some biologists also believe that strenuous courtship performances and extravagant male ornamentation may evolve to demonstrate vigor and resilience in the face of the parasite load that is borne by almost all wild animals (Fig. 4).

At a more general level of strategy, conservationists are caught in the same contradiction that afflicts all biological educators. On the one hand, simple messages are the most effective. On the other hand, life is irreducibly complex. The story of the Florida scrub jay, for example, is complicated enough without considering all the grasshoppers, beetles, millipedes, and other invertebrates that are also restricted to Florida scrub habitat. The choice is often made to focus on a few species whose protection through habitat preservation will automatically protect a large number of other species, such as terrestrial invertebrates. It may seem that this is an unscientific approach, one that panders to a perceived bias against small, crawling creatures. In reality, it may be more a question of available information—both scientific information and information that is part of our human heritage. The biology of the Florida scrub

FIGURE 4  The sucking louse, Phthirpediculus propitheci, is a parasite on the body of the endangered sifaka lemur, Propithecus diadema. This louse, which is indubitably endangered because of the status of its host, seems an ideal candidate for Gilbert and Sullivan’s “little list of society offenders who might well be underground, and never would be missed!” Maybe not, however, because sifakas, like most other primates, do much of their socializing during episodes of mutual grooming, and the removal of the stimulus for this interaction could change the intimate and supportive behavior of the species.
jay is known in great detail, including the complex of factors that threaten its existence, whereas the biology of the Florida scrub millipede is almost completely unknown. Likewise, almost everybody has an intuitive understanding of the significance of habitat loss to the Florida scrub jay because this bird, like our own species, is relatively intelligent, home-loving, hierarchical, territorial, and lives in nuclear families. Accurate and detailed communication about the world of the Florida scrub millipede is not currently possible. If one were to make the choice between studying a few endangered species in detail or studying many endangered species more superficially (a choice that few biologists actually make), it might make sense to study a few species in-depth (Fig. 5).

In the long run, however, the study of a great variety of endangered species provides a wealth of fine-grain information on management and biogeography that is omitted when pandas or tigers are used as "umbrella species" whose protection helps to protect thousands of species that share the same habitat. A portion of the earth’s endangered biota is contained in sites that do not support any endangered vertebrate species. The endangered blue butterflies of the genus *Maculinea* often occur in small sites in which there are no endangered vertebrates. Certain small islands near the larger islands of New Zealand lack remaining endangered vertebrates but have retained some endangered invertebrates. Perhaps this millipede also has some special microhabitat requirements.

III. THE SPECIAL PERILS OF SPECIALISTS

The very factors that have made the terrestrial invertebrates such a huge, successful group have guaranteed that large numbers of their species will become endangered as humans change and destroy natural habitats. The small size of terrestrial invertebrates has allowed them to specialize on miniature resources. Huge numbers of species, for example, feed on only one part of a single species or genus of plant. Many other species are internal parasites in a narrow range of insect hosts. The great advantage to this specialization is that it has allowed spectacular efficiency in finding and exploiting resources. The small bark beetle, *Cactopinus hubbardi,*
which raises its larvae in the injured tissue lining the cavities made by woodpeckers in saguaro cactus, only needs to deal with the nutrients and defensive compounds of one kind of plant. It is probably able to zero in on its breeding sites, which are unlikely to be numerous in any one area, by following an odor plume emanating from the injured cactus.

Since terrestrial invertebrates are able to rest in a dormant state with minimal energy expenditure, they can evolve life cycles synchronized with the availability of their resources, and this also increases the ability to specialize. The hundreds of species of solitary bees in arid habitats of Mexico and the southwestern United States can synchronize their emergence with the seasonal changes or the periodic rains that stimulate blooming in their plant hosts. This, combined with coevolution between the mouthparts of bees and the architecture of flowers, has led to many species-specific bee and flower relationships. The evolution of many specializations is driven by the benefits of greater efficiency and less competition accrued by specialists. When humans disturb natural habitats, however, extreme specialization is a liability for many inhabitants because even temporary loss of a resource can eliminate the species that depended on that resource (Fig. 6).

The small size of terrestrial invertebrates allows them to maintain thriving populations of habitat specialists in a small area, such as an isolated mountaintop with some alpine habitat that was colonized at the end of a glacial period. Evolutionary biologists believe that speciation is most likely to occur in such isolated populations peripheral to much larger populations. The isolated subspecies (really species in the making) of butterflies known as arctics (Oenis) and alpines (Erebia) show that this process can occur over a relatively short time. In areas in which there has been long-term isolation of habitat fragments, it is often possible to find isolated populations that have diverged so much that they are clearly distinct species that could never merge, even if they were brought back together. Some groups of flightless Orthoptera provide good examples of this process of speciation at work. Many of these distinctive forms and species of terrestrial invertebrates could persist indefinitely in the small areas of habitat where they now occur, but these species and forms can be considered endangered because they could easily be eliminated by an episode of habitat destruction that would be small by current standards (Fig. 7).

Terrestrial invertebrates as a group are not at risk because there are many species that are generalists or are widely distributed. A significant proportion of the total diversity of invertebrates, however, is composed of species that are highly specialized or restricted to one or a few small patches of habitat.

**IV. THE SIGNIFICANCE OF ENDANGERED TERRESTRIAL INVERTEBRATES**

A sparrow falls, Thou art mindful; A spider is gone, art Thou vexed?

Why should anybody be concerned about endangered terrestrial invertebrates? Some people view this as a question of ethics: They believe that Homo sapiens is not the only species with a right to exist, or they believe that it is wrong to rob all future generations of the rich biological heritage that was passed down to us. It is true that there have been previous waves of extinction...
FIGURE 7 In Florida a series of isolated ancient dune fields have their own species of grasshoppers that are unable to live in the surrounding lowlands. Since these upland sites escape the flooding that is common in lower areas, they are well suited for housing and agriculture, and these grasshoppers have much reduced habitat and at least three appear to be endangered. Distinctive endemic species such as these grasshoppers also serve as biogeographic indicators, showing that the areas they inhabit have been isolated for a long time and might have additional endemic plants and animals. The number of examples of endangered Florida invertebrates appearing in this article is due to my familiarity with these species; there are many examples of endangered invertebrates almost everywhere.

of invertebrates caused by such events as ice ages or perhaps the impact of asteroids. Ethics, however, denies to us the innocence of an ice sheet or shooting star. A foundation stone of ethics is that we must endeavor to understand and take responsibility for the consequences of our actions. Since our species is strongly guided by ethics, ethical considerations may be as real and important as the dictates of materialism. The origin and nature of ethical attitudes toward other species have been considered by several scientists, especially Edward Wilson. Even from a materialistic standpoint, however, it makes sense to be concerned about endangered invertebrates for a variety of reasons.

First, endangered terrestrial invertebrates may be viewed as repositories of information. Currently, we have neither the time nor the skill to interpret this information. Some endangered invertebrates might produce useful chemicals. They might have innovative defenses against fungi or bacteria. They might have peculiar genetic systems or developmental pathways that are easy to analyze. Endangered species might inspire new areas of microengineering. They might display a variety of physiological mechanisms to deal with extreme environmental conditions. They may present more detailed evidence of evolutionary trends. They may be convenient indicators of environmental change. They might have novel types of mutualistic relationships with other animals or with plants. They may be remnant populations of formerly abundant species with important roles in restored ecosystems. Introduced pests might be controlled by invertebrates that are rare or endangered in their homeland.

In addition to these potential material benefits, non-material attributes of endangered invertebrates could have their own materialistic spin. Humans are willing to spend prodigious effort and money on nonmaterial things, such as entertainment, aesthetics, or the opportunity to make new discoveries. Many endangered species of terrestrial invertebrates might achieve their highest value as examples of the beauty and intricacy of life; considering the psychological needs of our species, this is an offering that can never come too often or in too many guises. Already, the conservation of several species of butterflies is pushed by the market value of aesthetically pleasing specimens or of live specimens for butterfly houses that charge admission.

With regard to terrestrial invertebrates, we are currently in an inspiring but frustrating state of ignorance in which any useful quality that we can imagine may well be represented in the group, but our imaginations are clearly insufficient to the task.

Second, the things that we care about are often dependent on small, unconsidered details: the linchpin that holds the wheel on the axle or the knot at the end of the thread anchoring the stitching. From this truth, it is easy to postulate that there are ecological systems that are tenuously held together by endangered invertebrates. Good examples might be found in old, isolated systems with a very limited number of species, such as a cave or an oceanic island. The situations in which a single species has this linchpin role are likely to be few and exceptional. Most large-scale ecological systems, such as a large area of rain forest in New Guinea or desert in Arizona, must have impressive built-in versatility or they would not have survived the many natural changes affecting the planet before the advent of our species. On the other hand, biological systems of all kinds can only withstand a certain degree of stress. It is difficult to recognize the approach of a breaking point,
much less identify the relatively small events that could serve as triggers.

Third, although a single rare and endangered species of invertebrate is unlikely to determine the fate of a large ecological system, rare invertebrates may be important in the aggregate (Fig. 8). In the remaining natural habitats of the world, especially those in warm and warm-temperate climates, most of the total diversity of invertebrates is composed of relatively rare species. Many of these rare species could quickly become endangered species if their habitat changes in some major way. This change could be general habitat disturbance, or it could be habitat fragmentation. It could also be caused by extensive contamination by pesticides to control agricultural pests. Aerial application of pesticides to control biting insects is a special problem because a reduction in the incidence of human disease can be used to excuse even the most destructive of practices. Most insect-borne diseases, however, are cycling in heavily settled areas; they seldom sweep out of large tracts of natural habitat. In the future, invertebrates might be endangered by genetically altered plants or pathogens that carry self-replicating pesticides from agricultural areas into other habitats. One of the greatest threats to rare invertebrates today is invasion by exotic invertebrates. All these kinds of threats, which often occur in combinations, have a single general effect on ecosystems: They replace many specialized invertebrate species with a few generalists. The cumulative effect of this loss of invertebrate diversity may be to threaten populations of large, noticeable organisms, such as certain large vertebrates or plants. At a more basic level, however, much of the efficiency and precision of energy flow through ecosystems relies on the rarer and more specialized species of invertebrates, just as the efficiency and precision in our communication relies on the availability of a huge number of rarely used and specialized words.

FIGURE 8 General ecosystem functions, such as recycling of nutrients, are most efficiently done by many specialists rather than by a few generalists. The plates that cover the shells of tortoises are made of keratin—a protein that, because of its strong disulfide bonds, few scavengers can digest. However, there is a moth, Ceratophaga vicinella, whose caterpillar appears to have a specialized diet of the shells of dead gopher tortoises. There are innumerable specialized invertebrates that feed on particular kinds of wood, bark, dung, and carrion. No single one of these species is likely to be important in an ecosystem, but as a group they have a large impact.

V. NO SECOND CHANCES

Each species of endangered invertebrate is an old and irreplaceable entity. This seems like an obvious point, but one so often hears of “new” species of invertebrates that it is easy to unconsciously absorb the impression that invertebrates are evolving at a prodigious rate. These new species are always old species that are newly discovered. It is true that in special circumstances invertebrate populations can diverge relatively rapidly, evolving behavioral and physiological differences specific to the different conditions in different sites. Most invertebrate species, however, are distinguished by morphological specializations that probably took a long time to evolve. This can be seen by examining the fauna of recently formed islands, such as the Bahamas. The Bahamas were submerged by the sea about 135,000 years ago and emerged again approximately 100,000 years ago. Although 100,000 years is a long time by human standards, it is evidently short by evolutionary standards—insufficient for the evolution of a major group of Bahamian species of terrestrial invertebrates or terrestrial plants.

Recently, systematists (specialists who study the evolutionary relatedness of animals and plants) have put forward the argument that special attention should be given to endangered species that are the last remnants of evolutionary lines that largely disappeared millions of years ago. It is noted that these relics may have unusual kinds of adaptations and also provide glimpses
of ancient life on our planet. Certain endangered terrestrial invertebrates would be high on the list of species that would benefit from special consideration of relics: Onychophora, giant mites, redwood Thysanura, and many primitive lineages known from small areas of the tropics or south temperate areas. Although there is some logic to priority for the most ancient and conservative of the endangered terrestrial invertebrates, unless systematists are willing to work closely with ecologists, the identification of relict lineages is not very useful. Moreover, although ancient relics may be important for historical reasons and because they embody peculiar adaptations, they may have less relevance to modern systems than species that evolved from widespread lineages only a few million years ago. For example, useful natural enemies of pests of solanaceous crops (such as potatoes, peppers, and tomatoes) are most likely to be found among the large numbers of wasps and flies that attack insects on wild Solanaceae in some remnant habitat in the Andes Mountains.

In summary, terrestrial invertebrate species, once lost, cannot "reevolve," and the generation of new species that might restore lost diversity occurs on a time-scale too long to be relevant to our own species. Every year there are more species of terrestrial invertebrates than there ever will be again, even should human civilization endure 100,000 years.

Enemism

R. M. Cowling
University of Cape Town

GLOSSARY

biotope Region that is distinguished by particular environmental conditions (climate, soil, altitude, etc.) and therefore a characteristic assemblage of organisms.

stenotopic Referring to taxa with restricted habitat requirements (i.e., confined to a single biotope) and hence restricted distributions.

Endemic taxa are those restricted to a specified geographical area. Therefore, the concept is a relative one; the patterns, correlates, and causes of endemism will vary according to the size and location of the geographical area, as well as the taxonomy and phylogenetic relatedness of the assemblage under consideration. At a global scale, all taxa are endemic and there is relatively little to say on the topic. Most research has focused on species that are endemic to relatively small areas. In this sense, endemism is best viewed as a form of rarity, that is, range-restricted rarity. This article presents biogeographical, evolutionary, ecological, and conservation perspectives on endemism and discusses generalizations regarding the patterns, correlates, and causes of species-level endemism in relatively small areas.

I. CATEGORIES

Endemics may be categorized according to their spatial distribution, inferred evolutionary age, affinities, and local abundance.

A. Spatial Distribution

Endemics are loosely and commonly categorized in four contexts of spatial distribution: site or restricted area; biotope; biogeographical region; and political area.

B. Evolutionary Age and Affinity

Categorization of endemics according to evolutionary age and affinity is summarized in Box 1. These schemes have been widely used by botanists but rarely by zoologists. Problems associated with the schemes are that (1) age is regarded as a categorical rather than continuous variable; (2) the establishment of relationships among...
Box 1  
Categorization of Endemics According to Evolutionary Age and Affinities

A. Engler’s scheme, published in 1882.
1. Neoendemics: comprising clusters of closely related species and subspecies that have evolved relatively recently.
2. Palaeoendemics: comprising phylogenetically high-ranking taxa, usually monotypic sections, subgenera, or genera that may be regarded as evolutionary relicts.

R. C. Favarger and J. Constandriopoulos’s scheme, published in 1961. This scheme uses cytological data to provide a more rigorous basis for assessing the age and affinities of endemics.
1. Palaeoendemics: ancient isolated taxa with a high ploidy level, whose diploid ancestors are extinct or unknown.
2. Schizoendemics: vicariant species of equal ploidy level, resulting from either gradual or rapid divergence.
3. Patroendemics: restricted diploid species that have spawned younger, widespread polyploid species.
4. Apoendemics: polyploid endemics that are derived from widespread species of a lower ploidy level.

Schizo-, patro-, and apoendemics are further subdivisions of Engler’s neoendemics.

taxa lacks rigor; and (3) many palaeoendemics are diploid.

Phylogenetic methods, which consider the distribution of characters among taxa in a cladistic context, provide a rigorous categorization of endemics in terms of relative age and propinquity of descent. In this context, low-ranking taxa correspond to neoendemics and high-ranking taxa to palaeoendemics (cf. Box 1). An absolute estimate of the age of endemics can be given when congruent phylogenetic relationships correlate with identifiable historical events.

C. Local Abundance

The classical, biogeographical perspective on endemism has tended not to consider the local abundance of species. However, in the more recently developed ecological and conservation perspectives, in which endemism is conceived as a category of rarity, population abundance is invariably explicitly considered. Thus, geographical range size as a categorical variable (wide/narrow) has been used as one of the factors in defining seven forms of rarity recognized for plants. Endemics (narrow range) may belong to any four categories of rarity according to biotope specificity (broad/restricted) and local population size (somewhere large/everywhere small).

II. PERSPECTIVES

The concept of endemism has a long history in biology, dating back to A. P. De Candolle’s treatise, published in 1820. Most research on the topic has been in the field of descriptive biogeography, where distribution patterns of taxa have been used to define centers of endemism at various spatial scales. This approach provides a static perspective of endemism.

Over the past few decades, historical biogeographers have evaluated areas of endemism for monophyletic lineages in a phylogenetic context. This approach provides a dynamic perspective of endemism, especially when endemic taxa show congruent phylogenetic relationships that can be correlated with historical events. Evolutionary biologists, studying both fossil and extant biotas, have explored the role of range restriction as a cause and consequence of speciation. Recently, several statistical techniques have been employed—collectively termed the comparative method—to exploit the phylogenetic relationships among species to extract independent information on the evolutionary correlates of endemism. These techniques acknowledge that related species may have similar range sizes, that is, range size cannot be assumed to be independent among species. However, in at least some cases, variance in range sizes seems to be partitioned mostly at the species level.

Community ecologists have conceptualized endemism as one of several forms of rarity, namely, range-restricted rarity, and have explored its role as an explanatory variable for taxon-specific ecological traits, such as local population size, body size, reproductive fitness, and dispersal distance. Increasingly, they are using comparative methods to correct for phylogenetic relatedness among biotas. However, for every cause–effect relationship documented, there are numerous exceptions.

Conservation biologists view range-restricted rarity
as an attribute that predisposes a taxon to extinction. They seek to understand the abiotic and biotic correlates of this form of rarity as a basis for management guidelines that will reduce rates of extinction. A distinction is often, although not always, made between naturally rare species that may have some adaptation to rarity and those that have previously been widespread and are now restricted. Conservation planners often use patterns of endemism to identify reserve systems that are representative of a region's biodiversity. Many reserve selection algorithms have been formulated to select sites that have a unique or endemic complement of species.

III. MEASUREMENT

In quantifying patterns of endemism, the units of measurement (spatial scale and taxonomic entity), the mode of reporting of the data (percentages or counts), and a number of biases all influence the interpretation of the results. Of great importance is the relative nature of endemism: evaluation is always dependent on the spatial context and biological assemblage under consideration. This section provides a clarification of the problems and approaches associated with the measurement of endemism.

A. Units of Measurement

A variety of methods have been used to measure the range sizes of taxa. A useful distinction can be made between measures that attempt to estimate the extent of occurrence of a taxon—the distance between the outermost limits of a species' occurrence—and the area of occupancy—the area over which the species is actually found. The latter measure is particularly relevant for ecological studies that seek correlations between range size and environmental tolerances, as well as for conservation planning research; extent of occurrence is widely used in biogeographic studies.

Measures of endemism invariably seek to identify a subset of taxa within an assemblage that can be classified as having a lower than average range size. Within the biotas of larger-scale regions—biogeographic areas or countries—many researchers have recognized "local" endemics as a distinct category. However, the range size, or extent of occurrence, for defining this category is often arbitrarily set, varying between 50,000 km² (for Neotropical birds and plants, as well as for birds globally) to 2000 km² or less (for plants in the Cape Floristic Region). Endemics with extremely small range sizes—<5 km²—are regarded as point endemics. An approach that is increasingly being used is to evaluate endemism as a continuous variable, calculated as the sum of the inverse range sizes of all taxa in each quadrat (cell grid or map unit).

From both the biogeographical and ecological perspectives, patterns of endemism are best studied in relation to ecologically homogeneous, biogeographical regions. However, conservation planners often use political regions or property boundaries when evaluating endemism, since these may be the most effective decision-making unit for the preservation of endemics.

The taxonomic or phylogenetic scales employed also influence patterns of endemism. Centers of endemism identified on the basis of patterns among low-ranking taxa (sub-species or closely related species) often differ from those where the units are high-ranking members of the same lineage. Similarly, the spatial scale for defining endemism will vary among different taxa of the same rank.

B. Percentage versus Counts

Endemism may be expressed as a percentage of all extant taxa present, or as the absolute number of endemics in an area. Depicting plant endemics in biogeographic regions as percentages or counts, and using area and latitude as explanatory variables, results in different patterns with different significance (Fig. 1). Some species-poor areas, such as oceanic islands and arid regions, although low in actual numbers of endemics, may support a high percentage of endemic taxa. Others, such as Madagascar, the Cape Floristic Region, and parts of the Neotropics combine high richness and high endemism for some taxa. Ideally, both measures of endemism should be considered when explaining patterns, but seldom are.

C. Biases

Endemism is influenced by taxonomic interpretation, sampling error, and human perceptions of rarity. Of particular importance is the fact that limited geographical exploration, as well as variation in the application of taxonomic concepts, introduces biases in the identification of endemics and the significance of their status. Pseuendoendemics are widespread species incorrectly classified as endemics, whereas nonapparent endemics are endemic species that are incorrectly classified as widespread. The fact that widespread species are usually more thoroughly researched than those with smaller
range sizes introduces biases in studies that explore the correlates of range size.

IV. PATTERNS

There are very clear global and regional patterns of endemism for a wide range of taxa: endemics are not randomly distributed across the globe. However, these patterns are constrained by poor taxonomic knowledge and distributional data in key areas (e.g., the tropics) and for some taxa (e.g., most invertebrate groups).

A. Latitudinal Gradients

The incidence of endemism for whole assemblages in biogeographic zones increases with decreasing latitude (see Fig. 1). Range sizes, as measured by latitudinal extent, increase for a wide range of organisms above a latitude of approximately 40°–50°N, but the same patterns are not evident in the Southern Hemisphere. There are many patterns that are not consistent with the generalization—termed Rapoport’s Rule—that range sizes of taxa decrease with decreasing latitude, as a consequence of greater ecological specialization in less seasonal environments. For example, very high
endemism for terrestrial taxa is recorded in the mid-latitudes of the Southern Hemisphere, particularly in and adjacent to Mediterranean-climate regions. Marine teleost fishes have smaller range sizes at higher than at lower latitudes, and endemism for marine algae peaks in mid-latitude areas. These patterns are probably more a product of speciation and extinction processes than contemporary ecological conditions. Thus, widespread glaciation during the Pleistocene at high latitudes in the Northern Hemisphere resulted in the extinction of less tolerant terrestrial taxa. In mid-latitude Mediterranean-climate regions that escaped glaciation, rates of speciation, at least for plants, have overwhelmed extinction rates, resulting in an accumulation of habitat-specialist, range-restricted species.

B. Centers
Many centers of endemism—areas of higher than average concentrations of range-restricted taxa—have been recognized globally and regionally, principally for higher plants and large-bodied terrestrial vertebrate faunas. Generally, many groups of organisms show a concentration of centers at lower latitudes (Fig. 2). Following from the previous section, it is no surprise that the high-latitude areas of the Northern Hemisphere support few centers. However, this is not always the case in the Southern Hemisphere, where large numbers of range-restricted taxa occur in middle- to high-latitude landmasses that were never glaciated during the Pleistocene.

C. Congruence
Overlapping or congruent areas of endemism for different taxa have been used extensively by biogeographers to reconstruct historical events. Patterns of congruence of endemism are also important for identifying reserve systems that maximize the preservation of different biotas.

Although strong patterns of congruence have been recognized for some taxa at the global scale—for example, swallowtail butterflies and tiger beetles, amphibians, birds, and mammals—higher plant centers often do not coincide with faunal centers. Nonetheless, on the basis of congruent patterns of endemic species diversity for mammals, reptiles, amphibians, and higher plants, it has been possible to identify 17 “megadiversity countries” (Table I), that is, political units of high conservation value.

At a finer scale, patterns are highly variable among different taxa and in different regions, and no generalizations have emerged. This lack of strong congruence underlines the fact that endemism is an expression of many different causes, both ecological and historical.

---

V. CORRELATES AND CAUSES

Range size or degree of endemism shows some clear relationships with a wide array of abiotic and biotic factors. These correlations are very useful in conservation biology since they may be used to identify factors that predispose endemic species to extinction. However, correlates may be either a cause or a consequence of endemism. To identify the causes of endemism in an evolutionary context, comparative methods that exploit phylogenetic relationships must be employed. The causes of endemism are complex and numerous, and include intolerance of widespread habitats, niche specialization, isolation in marginal habitats owing to climate change, phylogenetic predisposition to narrow habitat selection, competition from alien species, and recent speciation of isolates in marginal habitats. Therefore, historical processes, contemporary ecological factors, and inherent biological properties of lineages are involved. In many cases, historical factors may be overriding, resulting in a poor relationship between measures of endemism and explanatory variables reflecting the contemporary environment.

Establishing correlates is a useful step in explaining patterns and causes of endemism. Most pertinent studies have addressed the following question: When compared to more widespread taxa, are endemics, however defined, a random subset of the biota with regard to abiotic and biotic factors? Developing these profiles, however, has been complicated by different definitions of endemism, multiple interactions between different traits, and a failure to consider phylogenetic relatedness.
This section provides a brief review of the abiotic and biotic interspecific correlates of narrow range size, and concludes with an assessment of the role of endemism in speciation.

A. Regional Species Richness
There is often a positive relationship between the incidence of endemism and regional-scale richness. This results from the importance of high habitat-related and geographical compositional turnover (beta and gamma diversity, respectively) in producing regional richness. Habitat specialists (or stenotopic species) and geographical vicariants often have narrow range sizes. However, there are also many cases where patterns of endemism and diversity are largely noncoincident. Examples include plants in the Neotropics, birds in the Andes, dragonflies and terrestrial vertebrates in southern Africa, and the biotas of many oceanic islands and deserts.

B. Area
As a generalization, proportionate and absolute measures of endemism increase with increasing area (see Fig. 1), irrespective of the taxonomic level. However, the relationship between number of endemic species (counts) and area is not as tight as that for the more widely studied species–area relationship. This results from the lack of congruence between endemism and richness in many areas (e.g., and lands and oceanic islands).

C. Abiotic Environmental Factors
Levels of endemism may vary in a predictable way along gradients of rainfall, temperature, productivity, and habitat heterogeneity. Models that accurately predict levels of endemism on the basis of easily measurable environmental variables have been used for the rapid identification of endemic-rich areas.

For higher plants, levels of endemism increase with increasing productivity, with increasing elevation (reflecting increased habitat heterogeneity and isolation in high-altitude areas), and with higher rainfall in low- and middle-latitude areas, although many exceptions to these patterns exist. In the Mediterranean-climate regions of the Cape and southwestern Australia, there is a negative relationship between local endemism and soil fertility. In the California Floristic Province, palaeoendemics are clustered in the wettest and driest areas, whereas neoendemics occur in transitional rainfall areas where rates of speciation are highest. Similar patterns exist for Afrotropical birds and Neotropical butterflies. For a wide range of marine taxa, endemism is more pronounced in exposed and variable nearshore environments than in the more stable distant-shore habitats.

D. Biotope
Geographically isolated areas and biotopes, such as certain islands, mountain peaks, ancient lakes, caves, thermal vents, hot springs, vernal pools, the abyssal zone, and chemically imbalanced substrata, support a disproportionately high number of stenontopic endemics.

Most studies have focused on endemism on islands, mountains, and unusual substrata. Generally, larger continental islands such as Madagascar, New Caledonia, and New Zealand support the greatest number and proportion of endemic taxa, especially of higher plants. Elevational range explains the incidence of plant endemism on the Canary Islands and bird endemism in Indian Ocean archipelagos, suggesting the importance of topographical diversity. Continental islands are typically rich in palaeoendemics, whereas some taxa have undergone extensive and unusual adaptive radiation on oceanic islands such as the Canaries and Hawaii.

Mountains are also often rich in endemics, in both tropical and temperate regions, but not in recently glaciated, high-latitude areas of the Northern Hemisphere. Many desert inselbergs (granitic outcrops) act as mesic refugia that support endemics, this is particularly pronounced for plants in middle Asia. As on islands, endemism on mountains results from both historical (e.g., isolation) and ecological (e.g., heterogeneity) factors.

The restriction of endemic plant species to nutritionally imbalanced substrata, especially when these occur in an islandlike configuration, is widespread in Mediterranean-climate and humid tropical regions. These sites provide both a strong selective force for the evolution of neoendemics and a refuge from competition for palaeoendemics. The restriction of animal taxa to unusual substrata has not been studied in any detail, but is likely to be a response to habitat effects on vegetation structure rather than nutritional peculiarities per se.

E. Biology
Very few studies have addressed the relationships between restricted range size and biological factors such as body size, growth form, life-history traits, population size, and genetic architecture. Of these studies, few have
considered multiple trait interactions or phylogenetic relatedness.

As a generalization, there is a positive, albeit weak relationship between a species’ range size and its local population abundance for a wide range of taxa (Fig. 3). However, not all endemics have low local abundances; indeed, many narrow plant endemics are extremely abundant locally. There are a number of hypotheses to explain the positive relationship between range size and local abundance. These are based principally on artefacts (e.g., sampling effects), resource use, metapopulation dynamics, and spatially independent rates of population growth. This pattern and its causes are currently attracting considerable attention.

There is a broad positive relationship between geographical range size and body size for animal species (Fig. 4). There is also a trend, both within regional floras and specific taxa, for low-stature growth forms to be overrepresented among plant endemics. This is especially true of the South African Mediterranean-climate region, where low shrubs (Fig. 5) dominate the endemic flora. Among Neotropical forest plants, endemics tend to be herbs, shrubs, or epiphytes rather than forest trees, whereas in the rain forests of Sri Lanka, endemics are overrepresented among long-lived, late-successional trees.

Gigantism is a common feature among some plant groups endemic to alpine habitats at low latitudes. Among animals, gigantism, dwarfism, and flightlessness are widespread among island endemics, as well as among some continental endemics associated with insular biotopes.

The reproductive correlates of endemism have been more extensively studied than other biological attributes. There are a number of pertinent generalizations, although exceptions exist for all of them. Range-
FIGURE 5  Percentage of endemic and nonendemic species in the Langeberg mountain flora (Cape Floristic Region, South Africa) in (a) seven growth form classes (G = geophyte, HG = graminoid, FO = forb, T = tree, LSH = low shrub, MSH = mid high shrub, TSH = tall shrub); (b) two postfire regeneration classes; and (c) four dispersal mode classes. Chi-square analyses were performed on untransformed data. (Reprinted from Biological Conservation 72, D. J. McDonald and R. M. Cowling. Towards a profile of an endemic mountain fynbos flora: Implications for conservation, pp. 1–12. Copyright 1995, with permission from Elsevier Science.)

restricted species differ from common ones in that they:

- tend to be self-compatible or rely on asexual reproduction;
- tend not to be wind-pollinated or have other inefficient forms of pollen transfer;
- invest less in reproduction;
- have poorer dispersal abilities;
- have shorter generation times.

The last two attributes are shown in Fig. 5, where short-distance ant dispersal and fire sensitivity (rapid generation time) are overrepresented among plant endemics in a mountain region of the Cape Floristic Region in South Africa. However, these and other reproductive traits, such as seed size, seed number, and reproductive investment, all interact in complex ways. Furthermore, these traits are not independently distributed among species.

Many studies indicate that plant and animal endemics have lower levels of genetic variation in comparison with widespread congeners. This may be due to several factors, including adaptations to narrow ecological conditions, small population size, and self-incompatibility in plants. However, there are also cases of little difference in genetic diversity between closely related endemic and widespread plant species.

F. Taxonomy and Phylogeny

Many biotas that are endemic to biogeographic regions are not a random phylogenetic assemblage. Some plant families are significantly overrepresented among the endemic floras in many parts of the globe, especially in Mediterranean-climate regions. The same is true of certain dragonfly families in southern Africa. Among plants, Cyperaceae and Poaceae are underrepresented as endemics in many floras throughout the world. In many cases, these patterns can be attributed to taxon-specific biological attributes that predispose a lineage to endemism. Thus, the existence of discernible phylogenetic correlates of endemism implies that range size may be an evolutionarily stable character of a lineage. Hence there is a need for the comparative approach to assess the role of phylogenetic relatedness in explaining patterns. However, it is important to establish the taxonomic level at which these relationships are manifested. For example, for several data sets, the majority of variation in range size is explained at the level of species within genera.
G. Endemism and Speciation

At face value, the relationship between range size and speciation appears to be quite simple: a reduction in range size will always accompany a speciation event, and a species nearing extinction—in an advanced stage of the taxon cycle—will occupy a limited range size. The deeper issue of the extent to which range size is a cause or consequence of speciation is a question of considerable interest.

There has been a long-standing and as yet unresolved debate regarding the causal relationship between range size and speciation. The arguments assume positive relationships between range size, population size, and dispersal ability. One viewpoint suggests that owing to extensive gene flow and reduced extinction rates, widespread taxa should have lower rates of speciation than range-restricted taxa. An alternative hypothesis is that owing to greater genetic variability and a higher frequency of founder effects, species that comprise large and well-dispersed populations that occupy large range sizes are prone to vicariant speciation.

Many studies of fossil and extant lineages suggest that turnover (speciation and extinction) is associated with relatively low local population abundance, poor dispersal, and narrow range size. Clearly, at extremely low values for these variables, extinction rates will overwhelm rates of speciation. Elevated speciation and extinction rates are also associated with increased specialization, reduced body size, and increased generation times; all of these are correlates of narrow endemism. Thus, endemism and its correlates are responsible not only for enhanced rates of speciation, but also rapid rates of extinction. In E. S. Vrba's parlance, these processes are flip sides of the same coin.

The alternative view, that speciation is associated with large, centrally located and widely-ranging populations, and that peripheral isolates are relictual taxa, also has support. Ultimately, aspects of this debate will be resolved by studies that assess range size and its correlates in a phylogenetic context.

VI. CONSERVATION

Because of their restricted geographical range size, high habitat specificity, and generally low population abundance, endemics are more vulnerable to extinction than are widespread and common species, as a result of both deterministic (habitat transformation) and stochastic (small population effects) factors. Therefore, considerable attention has been given to the conservation of local endemics. Attempts have been made to use the correlates of local endemism to devise management plans that will reduce anthropogenic extinctions.

Recent advances in systematic conservation planning have identified priorities for conservation on the basis of complementarity of biotas (representation), but also for the retention of biodiversity in the face of threatening processes. This approach involves the assessment of the irreplaceability of an area—a measure of the likelihood that the area will be needed to achieve a conservation goal—and its vulnerability to biodiversity loss as a result of current or impending threatening processes. Endemic-rich areas inevitably emerge as priorities since they combine high irreplaceability, owing to their unique biota, and high vulnerability, since endemics are prone to extinction. However, some endemics, particularly plants, may be preadapted to persist in small populations and could be effectively preserved in small, fragmented areas.

VII. CONCLUSIONS

There are few generalizations regarding geographical patterns and correlations of endemism. This is understandable, given that definitions of endemism are mostly study-specific, and that endemism is partly a consequence of regional-specific historical events acting on phylogenetically distinct biotas. Furthermore, species with similar range size often have different local abundances that are likely to be manifested in very different biological attributes. Finally, within-region analyses invariably lump together palaeoendemics and neoenemics, groups with different origins and phylogenetic relationships, and often, different biologies. The recent trend to correct for phylogenetic relatedness holds much promise for understanding the ecological and evolutionary correlates of endemism.

The most active fields of research currently are studies on the correlates of range size, particularly local population abundance, body size, and reproductive traits; the role of endemism in reserve selection, especially as a measure of irreplaceability and surrogate measure of vulnerability; and historical reconstructions using congruent areas of endemism in phylogenetic studies. Much less classical biogeographic research is being carried out on the identification of centers of endemism, despite the fact that reliable distribution data are lacking for many areas and taxonomic groups. This lack of data has serious consequences for the iden-
tification of endemic-rich areas for conservation purposes.

GLOSSARY

chemoautotrophs These microbes use inorganic compounds as a source of carbon and energy and function as primary producers.

decomposition The biotic breakdown of dead organic matter (detritus) by bacteria and fungi that releases carbon dioxide and nutrients for recycling.

ecosystems Composed of species assemblages (producers and consumers) that interact with each other and their associated abiotic environment within well-defined natural or conceptual boundaries.

food chains Composed of species that are connected by the flow of energy and material from producers to consumers.

food webs “Flow maps” that depict connections among multiple food chains.

functional groups Aggregations of species that perform similar ecosystem processes, such as grazers, suspension or filter feeders, leaf shredders, predators, and decomposers.

photoautotrophs These, such as green plants and some bacteria, use solar energy and inorganic compounds to synthesize organic matter as primary producers.

primary productivity The rate of synthesis of organic matter by plants (biomass per unit area of habitat per unit time or, in some cases, biomass per unit volume per unit time).

secondary productivity The rate of assimilation and growth by animals (biomass per unit area of habitat per unit time or, in some cases, biomass per unit volume per unit time).

trophic cascades These occur when changes in the presence or absence (or shifts in abundance) of a top predator alter the production at several lower trophic levels; primary and secondary production at lower levels are alternately constrained or unconstrained by the feeding activities of consumers at upper levels.

trophic levels Groups of individuals classified as primary producers or primary or secondary consumers within food webs; individuals feeding both as primary and secondary consumers are omnivores. A single species may be represented on more than one trophic level.

ECOSYSTEMS ARE THERMODYNAMICALLY OPEN, hierarchically organized communities of producers, consumers, and decomposers together with the abiotic...
factors that influence species growth, reproduction, and dispersal. These abiotic factors include the flow of energy and the circulation of materials together with the geological, hydrological, and atmospheric forces that influence habitat quality, species distributions, and species abundances. Energy flows through many species, and the way in which this flow affects the persistence of ecosystems is influenced by land-use changes, precipitation, soil erosion, and other physical constraints such as geomorphology.

Energy flow through ecosystems is essential for nutrients to cycle through food webs. These food webs are often subwebs of more complex species assemblages and may be only partial descriptions of more complex hierarchies of energy flows. The hierarchy of species' interactions in natural food webs typically results in some important feedback loops and recycling of nutrients and materials within the conceptually defined boundaries of an ecosystem. Many species of producers and consumers are usually interconnected and some may be interdependent. Food webs are diagrams that can function as "flow maps" to document which species interact with other species, either directly or indirectly, as energy flows through the community and determines the movement of nutrients and other materials.

Different species have important functional values, such as for organic matter production (plant and animal growth) or organic matter breakdown (decomposition), oxygen production, nitrogen fixation, and nutrient cycling. These species have intrinsic values as the unique end products of evolution, and native species are likely to have adapted specific ways to respond to local or regional environmental disturbances. Conceptually, the loss of even a single native species, or the introduction of a nonnative species, could alter how the other remaining native species continue to perform different ecosystem functions. Disruptions of ecosystem processes are known to have occurred after certain well-adapted, native species were lost through local extinction following intense (pulse) or prolonged (press) disturbances. However, predicting which species are essential to ecosystem functions has generally remained difficult because information is lacking on many species interactions as well as on life history, adaptations to different disturbances, and dispersal abilities among key species. Ecosystem studies can provide a broad perspective regarding species relationships and recycling of essential nutrients. Species' shifts in patterns of abundance (or local extinctions) following natural and anthropogenic disturbances illustrate how some key species regulate nutrient cycling and other ecosystem functions. Field testing of many concepts related to understanding the importance of key species in ecosystem functioning is just beginning. Results of these long-term ecosystem studies can provide guidelines for the stewardship of biodiversity.

I. ECOSYSTEM BOUNDARIES: INPUTS, OUTPUTS, AND TRANSFORMATIONS OF ENERGY

An ecosystem approach can be used to address many different questions spanning scales from the global biosphere to small ponds or patches of habitat. As the questions change, so do the boundaries and the complexities of species interactions within and among different compartments or across trophic levels. Ecosystem boundaries are often defined to include natural species assemblages and to analyze inputs and outputs of energy and materials for cross-site comparisons of efficiencies in energy transfers and studies of changing conditions. These analyses often take the form of mathematical models such as computer simulations or individual-based models of species and their specific functions within the biotic assemblage and environmental conditions under study. One ecosystem may export nutrients and organic matter (stored energy) to other ecosystems so that cross-site linkages often become important. For example, in studies of nutrient cycling in terrestrial ecosystems, the definition of boundaries would likely have some compartments of organic matter production by living plants and their relationships with herbivores and carnivores. Macro- and microminutrient inputs would likely be derived from the atmosphere through dry deposition of particulates—nitrogen gas being taken up by some nitrogen-fixing species of microbes. Other sources of nutrients, especially phosphorus, would come from weathering and erosion of soil and bedrock deposits, with movement among other compartments derived from actions of wind and water. This combination of interactions illustrates the importance of defining clear boundaries for subsystems within the complete ecosystem so that measurements of movements (fluxes) among compartments can be measured accurately. Generally, ecosystems and their boundaries are abstractions that can only be useful and insightful when combined with sufficient knowledge regarding the natural history and general ecology of communities and their physical environment. There is wide recognition that a combina-
tion of direct field observation, experimentation, and modeling is essential when conducting ecosystem studies. Currently, fundamental questions dealing with relationships between energy flow and the species-specific roles of organisms are attracting increased attention. For example, can results of controlled small-scaled (fine-grained) experimental studies of productivity be used to predict responses of other natural assemblages at larger scales (coarse-grained) of ecosystem dynamics? Does energy flow through an ecosystem increase, decrease, or remain the same if one species goes locally extinct but the abundances of other “similar species” change rapidly to compensate for the lost species? Under what environmental conditions do species substitute for one another and compensate functionally for the lost species? These and many other questions are beginning to be answered, but studies related to biodiversity and the persistence of species assemblages remain incomplete. A series of symposia during the 1990s dealt with the relationships between biodiversity and ecosystem functions (Fig. 1) and stimulated many new ideas (Schulze and Mooney, 1994; Orians et al., 1996; Lawton, 1997; Palmer et al., 1997; Naeem, 1998; Wall, 1999).

A. A Historical Perspective: The Ecosystem Concept

How energy moves from one group of species to another has been an active area of study at least since Charles Darwin and Alfred Russel Wallace first wrote in the 1850s about the interconnections among species. They were intrigued with the general proportions of population abundances that were thought to exist among different groups of large predators and their prey, and they emphasized competition and predation as important factors for regulating species interactions. These early observers lacked a conceptual approach to what was later viewed as ecosystem-level dynamics. Darwin’s studies of earthworms and their roles in soil development and his views on the roles of multiple species in the “tangled bank” metaphor stimulated others to consider how these many interactions could be viewed holistically. In 1887, Stephen Alfred Forbes described material cycles within lakes and used a table of predator-prey data to examine which fish species consumed similar or different prey species in Illinois rivers and lakes. Forbes drew his conceptual boundaries and predation matrix to coincide with the shoreline and emphasized putting the many pieces together in a type of system homeostasis in his new metaphor of the lake as a microcosm. This holistic view was taken up in a different way by E. A. Birge in 1915 with his work on heat budgets of lakes in Wisconsin. Birge measured inflows and outflows of energy, and in so doing he set the stage for viewing ecosystems in terms of their general physical attributes rather than numerous component parts. This “black box” approach allowed for observations at larger scales without full analysis of the controlling variables within the process under study. The British ecologist, Charles Elton, recognized that food chains existed in the context of energy flow and nitrogen cycling from his early work with V. S. Summerhayes on Spitzbergen and Bear Islands. The sum of these chains formed a food web which Elton called “food cycles” and included in a diagram combining nutrient cycling and energy flows over landscapes scales. Elton built on earlier concepts of Victor Shelford and introduced the idea of a “pyramid of numbers” and a “pyramid of energy” that reflected general patterns of community organization. More individual plants and plant material (biomass) can usually be harvested in a plot than herbivores or the relatively rare carnivores.

![Figure 1](image-url)
showing a rough resemblance to the growth curve of rate of production may be expressed as a sigmoid curve. This natural aging process was thought to reach a climax stage and undergo senescence before developing into a bog forest. Some of his thinking on patterns of productivity change through succession.

Lindeman emphasized that groups of species both "co-act" and "re-act" in their relationships with each other and with their abiotic environment. He further emphasized that these patterns of productivity change as the biotic and abiotic community develop over time through succession.

Based on his own detailed studies at Cedar Bog Lake, Minnesota (and other studies by Chauncey Juday on Lake Mendota, Wisconsin, who was actively studying lake productivity with E. A. Birge), Lindeman proposed that lake productivity increased during succession as nutrients accumulated in the basin during eutrophication. This natural aging process was thought to reach a climax stage and undergo senescence before developing into a bog forest. Some of his thinking on patterns of change in productivity over time was influenced by earlier studies by G. E. Hutchinson and Anne Wollack on Linsley Pond. Lindeman (1942) noted that their work suggested that "these generalized changes in the rate of production may be expressed as a sigmoid curve showing a rough resemblance to the growth curve of an organism or of a homogenous population" (p. 409). Such analogies between ontogeny of individuals, populations, communities, and ecosystems were commonly used during that time period. However, as more accurate data on rates of sedimentation became available and isotopic dating improved, the generality did not hold up and multiple patterns of lake eutrophication were later documented.

The concept of trophic dynamics and its focus on transfers of energy between trophic levels was not widely accepted until a new postwar influx of investigators began detailed studies of energetics. Several questions have persisted for decades: How can energy flow regulate the number of trophic levels within an ecosystem? How does one group of consumers regulate the number of individuals and energy flow in other trophic levels? These questions and many others were rapidly taken up by ecologists such as G. Evelyn Hutchinson, Eugene Odum, and Howard Odum and their students in the 1940s and into the 1970s.

After considerable debate and continued developments of the concept, many ecologists today rely heavily on models and field experiments using modifications of Lindeman's approach (Harlan and Harstan, 1997). Some still have concerns about fundamental issues regarding how trophic levels are defined relative to the complexities of natural food webs (DeRuiter et al., 1996). As a result, there are various definitions of what constitutes a trophic level. Because most descriptive field-based studies of food webs really study subwebs and therefore are incomplete, a thorough test of predictions regarding food chain length or long-term stability relationships derived from trophic models is usually not feasible.

Conceptually, the predictions of how energy flow regulates trophic dynamics are relatively straightforward. First, some of the initial energy entering the first trophic level is lost by reflectance from the plants, lost as heat, expended in metabolism and evaportranspiration, or lost because of a less than complete coverage of foliage (leaf area) or algal volume. Thus, some warming occurs by energy absorption by the physical habitat (e.g., soil, rock, or water). Then, from constraints imposed by the second law of thermodynamics, energy is lost at each step in the flow of energy from the first trophic level to successively higher levels within food webs. The use of solar energy or chemical energy by primary producers and the consumption of plants and animals at higher trophic levels are relatively inefficient because some energy is lost to metabolism and as heat at each transfer across trophic levels. The total energy flow through the plant trophic level is termed gross...
Empirical studies demonstrate that most food webs contain fewer than four trophic levels (DeRuitter et al., 1996). However, the number of trophic levels is not a consistent measure because of the complexity of feeding relationships over time and space, the mobility of consumer species, and the movement of food resources across ecosystem boundaries. Many species vary in how they obtain their energy and how efficient they are at different stages of their life histories and under different conditions. Among consumer species, many rapidly growing juveniles or reproductive adults require high-quality, nutrient-rich foods. These same individuals typically feed on lower protein foods when they become nonreproductive adults. Numerous species are omnivores and feed on plants and animals from different trophic levels. Because of these complexities, there has not been complete agreement on how to operationally define trophic levels.

The transformation of inorganic elements into organic matter requires energy to be converted into biomass by species of algae, green plants, and a few types of bacteria. These micro- and macroautotrophs are often represented by many species. The degree of similarity (niche overlap) in their abilities to produce and to store organic matter is important in predicting the consequences of any losses of species. Many species have evolved into persistent assemblages that store carbon and nutrients such as nitrogen and phosphorus. Energy stored in the form of plant-produced organic matter is later passed on directly to grazing species and then indirectly to predators within food webs.

Efficiency of energy transfer from one trophic level to the next higher level is of fundamental importance in understanding conceptually how different ecosystems function. Measures of efficiency, however, are only a part of the explanation for why some ecosystems have longer food chain lengths than others. Relatively "inefficient" food webs with few trophic levels appear to be adapted to certain types of frequent disturbances. Ecologists realize that a single explanation or mechanism is unlikely to account for all the various complexities that exist in determining how ecosystems are organized in terms of energy flow. However, comparisons among well-studied ecosystems and their numbers of trophic levels (food chain length) can provide a useful basis for predicting vulnerability of food webs to major disturbances (Orians et al., 1996) and movement of toxins such as mercury and other heavy metals.

Analysis of guilds and that of functional groups are different approaches used to study shifts in feeding behavior and to complement trophic-level analysis. Guilds are defined as assemblages of species or individual age classes that share a common source of energy at any given time (e.g., nectar-feeding birds and bees and insect-feeding birds and spiders). Functional groups are defined as being similar in their mode of feeding (e.g., filter feeders, shredders, and pursuit predators), but individuals may use a variety of different resources as resource availability shifts. Thus, individuals of a single species may be distributed over several trophic levels and belong to different guilds and functional groups during each individual's life span and reproductive period. As nutritional requirements change and the availabilities of different types of food resources also change, individuals can often adapt to find different available sources of energy. Analyses of similarities in these adaptations and the degree of overlapping functionality are used to understand the degree to which producer and consumer species are interdependent. Numerous complex linkages (e.g., herbivory, predation, decomposition, parasitism, and mutualism) imply that few species are likely to be complete substitutes for other species (Vest et al., 1995; Naeem, 1998; Covich et al., 1999; Crowl et al., 2000). As discussed later, some species may interact positively, negatively, or neutrally in association with other species. Such complex relationships among species, especially under changing environmental conditions, complicate field experiments and make predictive models difficult to test fully.
D. Controls of Energy Flow in Food Webs

A small increase in species richness can have a large effect on how energy flows through food webs. The main features are the number of linkages among species and, especially, the type and strength of those linkages (Paine, 1969). For example, a simple trophic structure would be a linear series of three species (A–C) in a food chain with one species in each trophic level (Fig. 2). Thus, a single species of plant is consumed by a single species of herbivore, which is consumed by a single predator species. Although analysis is relatively definitive in these types of communities with few species, this simple food chain structure may preclude consideration of some questions of general concern, such as resiliency of the assemblage following a disturbance and species loss.

If one more plant species is added (D) to a simple community, then this slightly more species-rich food web provides some important additional dynamics in terms of alternative pathways for energy to flow. Moreover, the herbivore (B) can switch from one food resource to another and this additional complexity increases generality and realism incrementally. With two herbivore species (B and C) the food web is more complex and the predator (A) has a choice of prey resources. Even with the same number of species, much more realism is added by considering the predator (A) to be an omnivore, and even more is added if the predator and one of the herbivores (C) are also cannibalistic. These simple diagrams show how quickly the types and numbers of linkages (connectance) within food webs can change the dynamics of energy flow even with only a few species. This last example is typical of some low-diversity stream food webs on isolated tropical islands currently under study (Covich et al., 1999; Crowl et al., 2000) and discussed later.

E. Ecosystem Analysis

General rules regarding the relationships between energy flow and the control of food web complexity are currently incomplete. In some habitats a complex relationship apparently does exist among the total annual amount (and seasonal distribution) of energy, the nutrient inputs to ecosystems, and the number of different species in a habitat. In other habitats there is no evidence for a cause-and-effect relationship among the rate of energy flow, species growth and productivity, and the number of species in an ecosystem. Other likely variables include evolutionary time and biogeographical distributions as well as the frequency and intensity of disturbances. The particular species composition of a food web may also alter productivity. Empirical evidence for predicting the importance of species-specific relationships is increasing, but methods for establishing which species regulate ecosystem functions remain controversial. Currently, only a few studies have focused on the species-specific roles to determine which species have unique roles and how these roles shift as environmental conditions change.

Although recent experiments have examined some fundamental relationships, we do not have a full understanding of the effects of varied energy inputs on the
richness of consumer species that naturally coexist in ecosystems. For example, in most tropical forests and coral reefs there is generally a high number of species, but the cause and effect of this species diversity are open to different interpretations other than the potential importance of relatively high and continuous inputs of energy (Waide et al., 1999).

At the earth’s surface the annual, seasonal, elevational, and latitudinal distribution of solar energy provides varied inputs of energy to deserts, grasslands, forests, wetlands, lakes, rivers, and oceans. Generally, energy always flows through ecosystems but does so at different rates under different global geographical locations and local conditions of slope and aspect. Depending on latitude, ecosystems generally receive a seasonally pulsed or a continuous annual supply of solar energy for primary producers. The rate of energy flow and associated biological productivity are dependent not only on the availability of energy but also on water, on combinations of different macronutrients (nitrogen and phosphorus) and micronutrients (trace elements such as iron, manganese, and silica), and on the presence of an assemblage of interactive plant and animal species. Some natural food webs in extreme environments, such as hot springs, saline lakes, caves, or certain deep-sea thermal vents, have relatively simple linear food chains and have species adapted for specific habitats. For example, dark, closed caves that are deep underground only receive indirect sources of detrital energy from sunlit surfaces aboveground and are typically characterized by a relatively low number of endemic species not found on the surface. Deep-sea thermal vents in the oceans rely solely on chemical energy derived from microbial breakdown of gases such as hydrogen sulfide and are characterized by sulfur bacteria and unique consumer species. These simple ecosystems continue to provide an opportunity to test some fundamental concepts regarding food webs and energy flow relationships.

II. MULTIPLE ENERGY PATHWAYS

It has been evident since Lindeman’s work that energy travels along different pathways and includes microbial species and macrospecies in various interconnected relationships. Experimental assemblages are now being widely used to provide some insights into which mechanisms control ecosystem dynamics. There is evidence for biotic control mechanisms (interspecific competition for resources, predation, parasitism, and mutualism), abiotic controls (nutrient limitation and frequent and/or intense disturbances), and combinations of controls in different ecosystems. These studies have also provided important insights regarding two main energy pathways. The distinction between direct, solar-driven, photosynthetically based food webs and indirect transfers of stored energy in the form of detritus (that can be wind driven or washed into habitats) has sorted energy flows into two main classes. The earliest work on ecosystems recognized this bimodal classification and it remains an important organizing framework in linking aspects of terrestrial and aquatic ecology (Polis et al., 1997; Covitch et al., 1999; Wall, 1999).

The importance of organic detritus as a means for storage of energy was recognized by studies of Jerry S. Olson in the 1960s at Oak Ridge National Laboratory on the carbon cycle. Analysis of time lags requires an understanding of how rapidly organic detritus accumulates and then breaks down to recycle carbon, nitrogen, phosphorus, and other materials. These insights are critical in current discussions regarding carbon dioxide accumulation in the atmosphere as fossil fuels are burned (i.e., coal, oil, and natural gas taken from storage that accumulated over geological timescales and are now being rapidly cycled back into the atmosphere following combustion). Debates regarding global warming, the greenhouse effect, and where the “missing” carbon is in the present-day ecosystem require a thorough understanding of the entire biosphere and the carbon cycle as it relates to other nutrient cycles.

Recent studies of deep-sea vents and hot mineral springs define a third distinct class of ecosystems that is not solar driven but depends on chemical energy sources used by chemosynthetic microbes. Geologic sources of hydrogen sulfide and other gases provide examples of chemical energy pathways that may well have been the first modes of ecosystem formation by the earliest microbial species on Earth before the evolution of photosynthetic species. Various lines of evidence, such as the banded iron formations in pre-Cambrian rock strata, indicate that the earliest atmosphere lacked oxygen, suggesting that chemosulfate microorganisms dominated the first phases of evolution. Once oxygen-producing photosynthetic organisms evolved and dominated the oceans and lakes (and later developed terrestrial forms of green plants), their high levels of primary productivity resulted in an accumulation of oxygen in the atmosphere and a decrease in carbon dioxide (possibly through carbon uptake and storage by plants and deposition of sedimentary limestones). This early shift into a phototrophically based ecosystem apparently put the chemosynthetic organisms at a competitive disadvantage in
A nutrient-rich lake ecosystem and the flow of energy and materials through major compartments. The inputs of dissolved nutrients and particulates (leaf litter and suspended organics) move through the lake ecosystem at a rate determined primarily by the amount of solar energy entering from the surface of the lake, the stored energy in the form of organic matter inputs (for bacteria, fungi, and detritivores), and throughflow of water. Productive lakes can be either sources or sinks of nutrients relative to downstream river and lake ecosystems, depending on their uptake and storage of energy and nutrients. Shallow lakes have a higher surface to volume ratio than deep lakes and are usually more productive because a larger proportion of their volume receives solar energy inputs. Winds mix nutrients from bottom waters and often circulate limited concentrations of dissolved phosphorus that flux from the deeper sediments. Energy transformations from solar input to green plants to herbivores and carnivores are essential for nutrients to move through the food web and be recycled (reproduced with permission from Covich et al., 1999).

A. Lake Ecosystems

To illustrate the flow of energy through ecosystems it is useful to consider some examples derived from lake studies. These convenient habitats have been used for comparative ecosystem studies because distinct boundaries provide clear definitions of inputs and outputs (Fig. 3). The main boundaries include any inflowing and outflowing rivers as well as the lake surface–atmosphere and the sediment–water interfaces and also shorelines and topographic ridges (that delimit drainage basins). Water temperatures, nutrient inflows and outflows, and mixing and transport processes all influence species distributions and abundances in generally predictable ways.

Solar energy transformed into organic matter through the process of photosynthesis is the main source of energy for most ecosystems, especially in large lakes. Different sizes and types of plants in lakes vary greatly in their rates of productivity. For example, in shallow-water ecosystems solar energy can be used by microphotoautotrophs (attached algae or suspended phytoplankton) and macrophotoautotrophs (pond weeds such as cattails and water lilies). The ratio of the biomass of organisms relative to their rate of production is termed “biomass turnover time.” Biomass is generally measured by multiplying the number of individuals in an oxygen-rich environment. These remnants of the earliest species of microbes now dominate only in deep-sea vents and hot mineral springs, in which they are still well adapted to compete.
a population by each individual's weight. Turnover time is related to how rapidly organisms increase in biomass during their life span. Rapid turnover is associated with high rates of productivity by small, fast-growing individuals of plants and animals. Small species with rapid turnover usually exploit resources at relatively fine spatial scales.

B. Importance of Depth and Spatial Heterogeneity

Different wavelengths of light energy penetrate into waters of different depths. Shade-tolerant species of plants living in deep water (or in deep shade of the canopy trees in terrestrial ecosystems) have distinct physiological adaptations that allow them to obtain sufficient energy to grow and reproduce even at low light intensities. The range of wavelengths that is used by plants is light visible to the human eye. This range of visible light (between approximately 400 and 700 nm) is termed photosynthetically active radiation. Short wavelength (ultraviolet light) and long wavelength (infrared light) are not used in photosynthesis but are important in regulating floating and emergent aquatic plants (or terrestrial plants in other ecosystems) because ultraviolet radiation degrades organic molecules and infrared increases leaf temperatures. Daytime warming from the sun is essential for some species to survive, especially insects and cold-blooded vertebrates (poikilotherms). Other transfers of solar energy are essential to various lake ecosystem processes (e.g., sediment and nutrient transport by wind and water). Work done by solar-generated winds mixes the lake and thereby influences nutrient cycling. Similarly, wind-driven currents disperse planktonic larvae and aereate deeper waters. Winds also increase salinity through evaporation.

Consumer species are limited by the availability of plant-derived organic materials (or microbially derived organic materials from chemosynthetic microorganisms). The well-mixed, brightly lit, open water (pelagic zone) is dominated by small species of zooplankton that are well adapted to feed on suspended phytoplankton. Microbial breakdown of dead organic matter (detritus or seston) and grazing on algae (by numerous invertebrate and vertebrate species) both function to recycle nutrients in the open waters. In other distinct habitats such as the shallow littoral zone near the shoreline, a vegetated zone is dominated by invertebrate species that feed on larger, rooted plants that have a slower turnover rate compared to the small, suspended algae. Some species of fish live in the littoral zone while young and move in and out of the pelagic open waters as they grow larger. As these predators increase in size, they switch from feeding on invertebrates and small fishes to consuming larger fish and crayfish prey.

III. INTERNAL AND EXTERNAL NUTRIENT CYCLING

Ecosystems are generally "open" with regard to external additions of nutrients from the atmosphere and from catchment basins. Deserts, grasslands, forests, and wetlands as well as most lakes and rivers continue to receive new supplies of nutrients from precipitation (rain and snow), from dust and eroded soils that are carried to the ecosystem by wind and water, and from human-derived fertilizers, sewage effluents, air pollutants, and other agricultural and industrial wastes. Decomposers recycle essential elements for continued productivity by other species. As a result of rapid decomposition, some ecosystems can be relatively "closed" in that nutrients may be rapidly recycled internally so that these nutrients remain within the ecosystem's boundaries and are not transported or lost to other ecosystems. Nutrients can recycle internally from temporary storage in living tissue (biomass), detritus, or storage in soils and sediments.

Different species of plants and consumers within the food web and specific environmental conditions (such as warm temperatures, low concentrations of nutrients, and high pH) influence rates of internal cycling. Land-use practices also have a large effect on vegetation and on how nutrients recycle within a catchment or move into streams and lakes. For example, by measuring the concentrations of nutrients in a stream draining forested catchments, a team of ecologists (led by Gene Likens and Herbert Bormann) identified different pathways for nutrients such as gaseous nitrogen and erosional phosphorus in Hubbard Brook, New Hampshire, from a series of long-term studies on the forest and its components (streams, lakes, and catchments). The research at Hubbard Brook demonstrated the importance of large-scale experiments (such as removal of forest vegetation) to determine how various components are related. The increased outputs of some major nutrients (nitrogen, phosphorus, and calcium) following the experimental manipulation of the forest cover provided information about the role of trees in taking up and storing water and nutrients. By tracking the movement of phosphorus out of the forest and into the stream, Judy Meyer concluded that pulses of stream flow were the primary...
ciliated protozoans. DOM is also a food resource for other microbial species, such as bacteria, fungi, and of microbes and is a source of energy and nutrients for ter (FPOM) is composed of small fragments of detritus (from leaves, fine roots, dead algae, and other small groups of specialized species that shred organic detritus internal nutrient cycling by using organic detritus as a source of energy. Their small size and fast turnover make them highly important. Bacteria and fungi rapidly break down dead organic matter before it accumulates within terrestrial soil and aquatic sediment (benthic) ecosystems. In many soil, stream, and estuarine ecosystems the amount of energy and nutrients cycled by microbes is relatively larger than that of the photosynthetic pathway. The soil and sediment biota have similar groups of specialized species that shred organic detritus (from leaves, fine roots, dead algae, and other small invertebrate consumers). Fine particulate organic matter (FPOM) is composed of small fragments of detritus and aggregates of dissolved organic matter (DOM) that form from breakdown products and from cell exudates and leachates in aquatic ecosystems (such as groundwaters, streams, lakes, and estuaries). The release of DOM and inorganic nutrients is accelerated by some species of microbes and is a source of energy and nutrients for other microbial species, such as bacteria, fungi, and ciliated protozoans. DOM is also a food resource for larger invertebrate consumers and provides a parallel set of pathways for energy flow. Invertebrate detritivores break down dead organic materials to obtain their energy. Many detritivores are dependent on microbes to condition the detritus before it can be consumed by invertebrates or vertebrates. Nutrient cycling allows for continued energy flow through the ecosystem. The continued input and flow of energy through the food web is likewise required for nutrient uptake and recycling. Numerous species of bacteria and fungi form a ‘microbial loop’ that provides for high rates of energy flow by breaking down organic matter. Excretion of wastes by consumers provides one source of nutrients for species in the microbial loop. The microbial loop is especially important in marine and freshwater pelagic (open-water) ecosystems. For example, a crater lake (e.g., Crater Lake, Oregon) with a limited surface area and positioned in a volcanic depression usually has a very small drainage basin compared to large lakes with extensive drainage runoff. A lake with a small surface area will also receive very little atmospheric inputs of nutrients. Primary production remains low and mostly dependent on rapid, internal recycling of nutrients from fine, suspended detritus (dead plankton) as a result of breakdown by microbial species. Nutrients may only slowly accumulate in the sediments of the deep crater lake and not be mixed by currents back into the upper layers of well-lit waters (photic zone). Whenever nutrients are low (as in midsummer in some more productive lakes following the spring bloom of algae) the role of microbes and invertebrate species in cycling nutrients is important to maintaining energy flow in the ecosystem. Similarly, nutrient concentrations are relatively low in the open ocean, far away from continental sources of nutrient runoff and from coastal upwellings of deeper, nutrient-rich waters. Microbes attach to dead plankton and use this organic detritus as a source of energy. In the process of breaking down this fine detritus, the microbes release nutrients for further growth by photoplankton (floating algae). Nutrients are also released in the photic zone by leakages from algal cells and by excretion of herbivores. The small size of the detritus particles slows their rate of sinking through the well-lit photic zone and allows the microbes to release nutrients where photoplanktonic photosynthesis is not light limited. Larger pieces of detritus fall more rapidly and accumulate in deeper, darker waters where short-term seasonal storage occurs. The nutrients in these deep, dark waters are not available for continued photosynthesis until this entire layer of nutrient-rich water is mixed vertically by wind- and gravity-driven currents.
back into the photic zone and taken out of temporary, seasonal storage. In very deep lakes, the wind energy is insufficient to mix the entire volume and nutrients accumulate over many years in these deep waters.

There are also some important horizontal linkages in that nutrients and organisms (especially differently sized fishes and wind-driven currents carrying drifting zooplankton) move from the shallow, nearshore waters (littoral zones) of lakes to the open waters (pelagic zones). In these surface waters, nutrients are also recycled by the grazing zooplankton (feeding on phytoplanktonic algae) and by consumption of zooplankton and phytoplankton by fishes. These nutrients are returned to the well-illuminated surface waters, where they are again available for continued algal growth.

This series of vertical and horizontal transformations of organic detritus and primary production of algae in the pelagic zones has some similar analogs in streams, in which the dynamics occur mostly horizontally, but to some extent vertically, along the network of stream channels. The combined vertical and horizontal currents in stream channels form a spiral in the downstream flow of water that carries nutrients and organisms various distances. Dissolved nutrients move in and out of solution as they are briefly taken out of solution by adsorption on sediments and by active uptake by microbes and attached algae (growing along the bottom of the channel), and are later consumed and released back into the water by cell leakage, excretion from grazers, and predatory fishes. This spiral pattern of nutrients being transported downstream while moving in and out of sediments and organisms and then taken up again by other organisms or adsorbed onto sediment particles farther downstream was first examined by ecologists at the Oak Ridge National Laboratory using isotopes to trace pathways and is now widely studied, for example, with stable isotopes of nitrogen (N\textsuperscript{15}). The distance that a particular nutrient element such as nitrogen moves downstream is termed the “spiral length.” If the nutrient is taken from solution and tightly held in different species’ biomass, then the spiral length is relatively short and the role of microbes and other organisms along the channel is relatively important compared to that for streams where biotic interactions are less significant and during other periods when the spiral length is longer.

Use of functional groups such as shredders and filter feeders (or scrapers, burrowers, and predators) allows for analysis of groups of different species in terms of particular attributes (e.g., how each species processes different sizes of detritus). In both vertically and horizontally structured interactions, the processing rate of organic detritus by microbes is accelerated by the presence of those invertebrate species that convert large organic fragments into finer fragments. If one species (shredders) uses larger sizes of suspended particles and breaks them down into smaller particles as a result of its feeding, then the downstream supply of FPOM is increased for use by other species (filter feeders). However, if the species that shreds detritus is lost, the filter-feeding species may not function effectively. Different species may form “processing chains” that require particular combinations of linked-species to complete certain ecosystem processes efficiently. These processing chains are one way that increased species diversity can increase efficiency of processing detrital resources, especially if detritus is available at low levels of abundance or if the detritus quality is low. Similar linkages are known to occur among burrowing organisms in soils and sediments where strong interactions are generally important in understanding how different ecosystems function (Wall, 1999).

IV. BIODIVERSITY EFFECTS ON ENERGY FLOW

Productivity and related ecosystem processes such as nutrient cycling and decomposition are generally known to be influenced by particular species. Species attributes, including length of life span, rates of dispersal, and tolerance of frequent and intense disturbances under various environmental conditions, have important effects on ecosystem processes. Key processes (such as nitrogen fixation) performed by only a limited number of species or particular modes of feeding characteristic of only a few species are recognized as important characteristics associated with biodiversity (Palmer et al., 1997; Covich et al., 1999). The importance of a single species in biogeochemical cycling was demonstrated by Peter Vitousek and his students in studies of the invasion of some habitats in Hawaii by the nitrogen-fixing plant Myrica faya and by determining the long-term consequences for nitrogen cycling and impacts on the ecosystem.

David Tilman and others conducted several experiments to test the hypothesis that primary productivity in prairie grasslands is related to the number of species of plants grown in the same plot. These experiments and others have the advantage of considerable replication and careful controls but were conducted at relatively small scales. Although the relationship between species richness and energy flow in ecosystems has
attracted considerable study, the scale of these experiments and the composition of the species assemblages studied have resulted in different interpretations of general relationships. Results of field tests suggest that the number of species per se is apparently not as important as the particular attributes of different species that relate to their efficiency of nutrient uptake and retention, as well as growth. The larger the number of species included in a study, the more likely some species will be included that are well adapted for the conditions and function effectively. Thus, although ecologists have conducted field tests to determine how different species alter ecosystem processes, there is no complete consensus on how energy flow by itself influences species richness or vice versa (Tilman et al., 1998; Waid et al., 1999). Part of this lack of consensus is a result of using different scales and methods in field studies of many different types of ecosystems (e.g., boreal and tropical forests, grasslands, deserts, deep and shallow lakes, and large and small rivers). Theoretical and conceptual developments are being actively developed and are stimulating additional field testing of these relationships between biodiversity and productivity.

A. Top-Down and Bottom-Up Regulation of Energy Flow

In the 1980s, some of the first experiments designed to identify the importance of different species and key attributes included the removal of predators. Because top predators are relatively few in numbers, their removal can be operationally feasible over some relatively large areas. Robert Paine removed predatory starfish from the intertidal zone and observed a shift in the relative and absolute abundances of some of the mussels prey species. His results demonstrated that competing species can be held in check by selective predation, especially if the predators consume more individuals of the more numerous prey species. Work by James Estes in the 1970s on the effects of declines in abundances of sea otters and increased abundances of sea urchins and other prey (as well as the shifts of algal regrowth in kelp beds) along the west coast of North America also demonstrated that predators had large effects on entire food webs. These “keystone species” were viewed as important regulators of energy flow in natural food webs in that they had a disproportionate effect despite their relatively small numbers or biomass.

Recognizing the importance of keystone species led some ecologists to use this idea for managing certain ecosystems. Researchers introduced the concept of bio-manipulation to study different combinations and abundances of algal species and grazing species in order to regulate nutrient cycling in aquatic ecosystems. In a series of lake studies by several ecologists (especially Joseph Shapiro, J. Hrbacek, John Brooks, and Stanley Dodson), they controlled the presence or absence of top fish predators. From these studies it became apparent that consumers in upper trophic levels could regulate populations of prey, and this regulation in turn had consequences for lower trophic levels as well as nutrient cycling. Manipulating consumer species as a means of removing algae or altering the uptake and storage of nutrients became an area of active study in order to manage lakes and improve water quality. These types of food web studies were also recognized as a means to monitor and to understand movements of toxic compounds such as DDT and mercury in lake ecosystems. Studies of introduced predators by Paine and Zaret further emphasized that nonnative predatory species disrupted food webs. However, some ecologists argued that native predators rarely altered prey populations or shifted species composition. Steve Carpenter and James Kitchell demonstrated that these species changes did occur in open-water food webs of temperate lakes. Certain fishes could selectively remove large-sized zooplankton grazers (as Brooks and Dodson had earlier demonstrated), resulting in increased biomass of phytoplankton and decreased levels of dissolved nutrients in a trophic cascade (Carpenter and Kitchell, 1993). In other lakes additions of certain predatory fish species had major effects on phytoplankton growth and nutrient cycling through the predators’ effects on grazers. Carpenter and Kitchell performed a series of whole-lake experiments to show that fish predation altered zooplankton species composition and size spectra. Shifts in sizes and types of zooplankton herbivores (and other invertebrate predatory species) in turn altered the phytoplankton community and its productivity. These trophic cascades have mostly been observed in aquatic ecosystems (Carpenter and Kitchell, 1993; Power et al., 1996). Recent studies, however, in a tropical forest demonstrate top-down effects through four trophic levels.

Many studies have demonstrated that bottom-up control by nutrients also influences the rate of energy flow in food webs. For many years, additions of nutrients were known to increase phytoplankton biomass and to alter species compositions of algae. Zooplankton abundances and species richness, in turn, often decline when the quality of their algal food resources is reduced. Thus, the distinct pathways of energy flow are altered by the amounts and proportions of nutrients available.
to algae and bacteria. High phosphorus concentrations lead to phytoplankton communities dominated by blue-green algae (cyanobacteria) because some species of blue-greens can fix nitrogen (incorporate it into their cells) from nitrogen gas in the atmosphere. Their capacity to use high amounts of both phosphorus and nitrogen allows them to outcompete species of green algae and diatoms that cannot use atmospheric sources of nitrogen. Blue-greens can also take up and store nutrients internally beyond their metabolic needs for nutrients and deprive other species of recycled nutrients. Many species of blue-greens have distinct features (slime sheaths, toxins, and large sizes of colonies) that make them relatively unpalatable to many grazers. Some species of blue-greens produce toxic substances. By avoiding grazers, blue-green algal species can grow rapidly in the upper waters of lakes and ponds, thereby shading out the competing species. Blue-green algae often form long, chain-like colonies of cells that are less readily filtered by certain species of large zooplankton. Thus, zooplankton production often declines in waters dominated by blue-greens, and with fewer large zooplankton available as prey the production by fish predators also declines.

In many ecosystems a combination of top-down and bottom-up control can be expected. The roles of specific species in determining how nutrients are used and how rapidly energy flows through different food webs are being studied. The generality of these complex relationships and the predictability of patterns of food web responses to additions of nutrients or the additions or deletions of predators are not completely established. There are some traits that appear to increase the likelihood of certain patterns, and these are under intensive study. For example, as plants and animals die and sink into deep, density-stratified lakes the breakdown of organic matter releases nutrients that can accumulate and dissolved oxygen can be depleted. Deoxygenation sets up chemical conditions in the sediments that release previously bound nutrients that are added to bottom waters. During mid- or late summer nutrients will be scarce in uppermost most brightly lit waters (photic zone) in temperature-density-stratified lakes because essential nutrients have become increasingly concentrated (during the spring and early summer growing season) in the lowest layers of water below the photic zone. With these accumulated nutrients stored seasonally in deep waters in which light is limited and nutrients cannot be taken up by plants, the roles of grazers and predators are less likely to control nutrient dynamics. Biomass manipulation of consumer species may be more effective in shallow, frequently wind-mixed lakes and ponds.

B. Stressful Environments as Testing Grounds: Ecosystem Services and Biodiversity

In some ecosystems the number of producer and consumer species is relatively low because they are adapted to severe environments. Similar situations can occur on isolated islands or in deep caves or hot springs. Only a few species can tolerate the physiological stresses associated with very high or low temperatures or highly variable or extreme salinities, acidities, or nutrient concentrations. Such sites are useful for conducting field experiments because the low number of species can be studied in detail and manipulated over relatively brief periods.

Because of their distance from mainland sources of colonizing species, headwater streams on tropical islands contain a few abundant species of freshwater decapods (shrimp and crabs) and only a few species of other detritivores. Recent studies in streams on Caribbean islands illustrate how species differ in their effectiveness as leaf shredders. Furthermore, these studies show that different species form processing chains and interact to transform suspended organic detritus into benthic biomass that is retained within headwater food webs rather than being washed downstream or accumulating in deep pools.

Whole-pool experiments (Covich et al., 1999; Crowl et al., 2000) in the Luquillo Experimental Forest on the island of Puerto Rico were used to study rates of leaf litter processing. Leaves of Cecropia schreberiana were placed into pools that were cleared of other detritivores. To start the experiments, either Xiphocaris elongata or Atya lampes were placed into the treatment pools in which other detritivorous shrimp had been removed. Controls were pools with Cecropia but with no shrimp. Downstream concentrations of suspended fine, medium, and coarse particulate organic matter, dissolved organic carbon, total dissolved nitrogen, nitrate, and sulfate were measured during 23 days. Results of the experiments illustrate how differently these two species function as detritivores. Both species of shrimp accelerated leaf breakdown rates relative to controls where only microbial breakdown occurred. Xiphocaris shredded Cecropia leaves much faster than Atya. Xiphocaris rapidly shredded the large, intact Cecropia leaves and converted them into fine suspended particulates. Xiphocaris increased the rate of downstream export of particulate organic matter and concentrations of total dissolved nitrogen and dissolved organic carbon relative to controls. These differences in
processing rates also affected downstream distributions of suspended particulate organics and nutrients. Atya increased rates of leaf breakdown less than did Xiphocaris and apparently filtered out fine organic particulates resulting in less downstream export. Atya are especially well adapted to shred conditioned leaves and to scrape microbes from leaf surfaces at low flows. Atya are also well adapted with highly modified cheliped fans to filter suspended organic particulates from the water when flow rates are higher than 20 cm/sec. Although both of these shrimp are detritivores, they are not complete substitutes for each other. Their co-location and relative abundances affect rates of detrital processing when they form detrital processing chains.

V. WHY SPECIES MATTER

Recent studies have demonstrated that some ecosystem processes apparently do change as the number of species increases (Tilman et al., 1998). One of the most cited examples is the relationship between increased numbers of species in mixtures of annual plants that are grown in experimental plots. The total area of the plot covered by plant growth (an indirect measure of primary productivity) increased as the number of species increased from 1 to 24. The mechanisms for this relationship are not clear, but progress is being made in interpreting the effects of species composition on these and similar replicated experiments dealing with primary productivity (Hector, 1998).

Linking species to different ecosystem processes (such as productivity and decomposition) highlights the importance of how organisms interact. In some cases, these interactions may facilitate how rapidly processes occur. For example, decomposition of organic matter prevents buildup of organic detritus, which could lead to increased or reduced growth of macrophytes depending on the amounts and types of litter. In other cases the role of different benthic species in breaking down litter can prevent deoxygenation of lakes and streams and maintain supplies of clean water (Covich, 1993).

VI. FUTURE STUDIES

Given the rapid and accelerated loss of species and the irreversibility of global extinction, it is imperative that experimental and conceptual studies do more to examine multiple levels of ecological organization, from populations and communities to ecosystems and landscapes, before more species are lost. Unfortunately, we lack sufficient information about how the loss of different species can disrupt natural ecosystem services. These losses represent a type of “warning light” that should draw more attention to analyzing the consequences of losing native species and introducing nonnative species that may disrupt ecosystem dynamics.

Improved techniques using stable isotopes, enhanced computer models, and many other developments have expanded the means of addressing ecosystem questions. However, only recently have ecologists evaluated the importance of species-specific attributes in ecosystem processes. Part of the reason for this slowness is that complete food webs are complex and dynamic. Furthermore, the specific functions of a single species are difficult to isolate from the functions of other species in most natural communities. Probably the most important factor has been the development of different scientific perspectives by population ecologists, community ecologists, and ecosystem ecologists. The recent emphasis on integration across disciplines has created a new perspective on the importance of different species’ roles in performing different ecosystem “services” or functions, such as nutrient cycling and productivity.

GLOSSARY

energy The capacity to perform work. Potential energy is this capacity stored as position (e.g., in a gravitational or electromagnetic field) or as structure (e.g., chemical or nuclear bonds). Kinetic energy is this capacity as manifested by the motion of matter. The joule (J) is the common SI unit of energy, where 1 J equals the amount of energy required to increase by one Kelvin the temperature of one gram of water. Other units include kilocalories (kcal), kilowatt-hours (kWh), and British thermal units (BTU).

energy, industrial Forms of energy generally transformed in bulk at centralized facilities by means of complex technology. The major forms of industrial energy are oil, coal, natural gas, nuclear, and hydroelectric. In addition to hydroelectric, industrial energy also includes other technologically complex methods of harnessing renewable energy, including photovoltaics, electricity-generating wind turbines, and geothermal turbines.

energy, nonrenewable Forms of energy whose transformation consumes the energy source. The major forms include oil, coal, natural gas, and nuclear.

energy, renewable Forms of energy whose transformation does not consume the ultimate source of the energy, harnessing instead solar radiation, wind, the motion of water, or geologic heat. The major forms of renewable energy are solar, biomass, wind, hydropower, and geothermal. The forms of renewable energy that depend on complex technology are forms of industrial energy. The simpler renewable systems are forms of traditional energy.

energy, traditional Forms of energy generally dispersed in nature, renewable, utilized in small quantities by rural populations, and often not counted in government statistics. The principal forms of traditional energy are firewood, charcoal, crop residues, dung, and small wind and water mills.

energy efficiency A measure of the performance of an energy system. First law efficiency, the most commonly used measure, equals the ratio of desired energy output to the energy input. Second law efficiency equals the ratio of the heat or work usefully transferred by a system to the maximum possible heat or work usefully transferable by any system using the same energy input.

entropy A measure of disorder or randomness at the microscopic level. The entropy of a completely ordered system (e.g., a system at a temperature of absolute zero) is zero.

fossil fuels Forms of stored energy produced by the action of pressure and temperature on organic matter.
buried over geologic time. The major types of fossil fuels are oil, natural gas, and coal.

law of thermodynamics, first Physical principle that energy is neither created nor destroyed, only converted between different forms. Energy is therefore conserved. In thermodynamic terms, the change in energy of a system equals the difference of the heat absorbed by the system and the work performed by the system on its surroundings.

law of thermodynamics, second Physical principle that any system will tend to change toward a condition of increasing disorder and randomness. In thermodynamic terms, entropy must increase for spontaneous change to occur in an isolated system.

power The rate of energy transformation over time. The watt (W) is the common SI unit of power, where 1 W equals the power expended by the transformation of one joule in one second.

HUMAN ENERGY USE is the extraction, collection, harnessing, and conversion of energy into forms that available technologies can utilize. Our energy use directly alters patterns of biodiversity through changes in land use and through industrial pollution. Indirectly, human energy use is changing global biodiversity through the emission of greenhouse gases that cause global climate change and through other broad environmental effects of industrialization. Whereas the direct effects cause acute damage, the indirect effects generally induce chronic harm. Because human energy use is equivalent to the product of population, per capita economic production, and energy use per unit of economic production, each of these factors can exert an equivalent indirect impact on biodiversity. Several other chapters in the Encyclopedia of Biodiversity cover important topics closely related to human energy use. Consequently, this chapter focuses on issues most unique to human energy use. Related entries include Acid Rain and Depositions; Air Pollution; Economic Growth and the Environment; Greenhouse Effect; Pollution, Overview.

I. PATTERNS AND SCALE OF HUMAN ENERGY USE

We use energy both to meet our subsistence needs and to satisfy our wants. In a subsistence society, a farmer's wife will burn wood to cook the day's meals. In an industrial society, a couple will jump in the car on Saturday night to go to a movie. Yet the forms of energy involved in these activities—wood, gasoline, electricity—constitute just the means to desired end-uses—cooking, driving, operating a theater—that ultimately provide unique services—food, transportation, entertainment.

As used by humans, energy falls into two broad categories: industrial and traditional. Industrial energy includes those forms of energy generally transformed in bulk at centralized facilities by means of complex technology. In general, these forms fuel the technology developed in the two-and-a-half centuries that have passed since the Industrial Revolution. The major forms of industrial energy are oil, coal, natural gas, nuclear, and hydroelectric. Industrial energy also includes other technologically complex methods of harnessing solar radiation, wind, and heat, including photovoltaics, electricity-generating wind turbines, and geothermal turbines.

Traditional energy includes those forms generally dispersed in nature and utilized in small quantities by rural people. The principal forms are firewood, charcoal, crop residues, dung, and small wind and water mills. Humans most depended on these forms of energy in the early stages of the development of the species. Because traditional energy sources occur widely and because their transformation does not rely on complex technology, they constitute the most important sources today for rural people in the less industrialized parts of the world. In most cases, a rural household will harvest its own traditional energy sources for its own needs. Because no commercial transaction occurs in these situations, and because most governments do not regulate the use of traditional sources, official statistics do not closely track traditional energy use.

Traditional energy is one form of renewable energy, which includes those forms of energy whose transformation does not consume the ultimate source of the energy. Renewable energy harnesses solar radiation, wind, the motion of water, or geologic heat. The major forms of renewable energy are solar, biomass, wind, hydropower, and geothermal. Conversely, the nonrenewable energy systems consume the very source of the energy, most notably, oil, coal, natural gas, and nuclear fuel.

Besides traditional energy and industrial hydroelectric energy, renewables include a host of recently developed, sometimes technologically complex, methods of harnessing sunlight, wind, water, or heat. These other renewable energy forms include photovoltaics,

The world uses renewable energy sources for only one-fifth of its energy use. The main renewables and their approximate rates of use are firewood and charcoal (0.7–1.1 TW), large hydroelectric (1 TW), agricultural crop residues (50 GW), biomass electric (23 GW), small hydroelectric (20 GW), wind electric (8 GW), geothermal (7 GW), urban waste (1 GW), biomass methane (1 GW), energy crops (500 MW), and photovoltaics (400 MW).

Figure 1 shows the tremendous increase in world energy use over time. In the 20th century alone, energy use has increased by a factor of 12. While total biomass use has remained constant, the world has witnessed an explosion in the use of fossil fuels. Figure 2 shows the share of the United States in world population, economic production, and industrial energy use in 1997. Although the United States hosts
FIGURE 2. Share of the United States in world population, economic production, and industrial energy use in 1995 (data from the World Bank and IEA 1997a, 1997b). (a) Population. (b) Gross national product (GNP) adjusted for purchasing power parity (PPP). (c) Industrial energy use. (This total of 11.8 TW counts only the energy output of hydroelectric generators. Counting the equivalent input if the electricity were produced by nonrenewables, the method used in Table I, would increase the total to 12.2 TW.)

only 5% of the world’s population, it generates 21% of the world’s economic production and uses 25% of the world’s energy. The average 1995 industrial energy use per person in the United States of 11,200 W cap1 greatly exceeded the world average of 2000 W cap1, as well as the industrial energy use in other industrial countries, such as the United Kingdom at 5400 W cap1. On average, each American uses 10 times the amount of energy as each person in the People’s Republic of China (3000 W cap1) and 30 times the amount of energy of each citizen of India (370 W cap1). Figures 3a and Figure 3b show the 10 countries with the highest and the 10 countries with the lowest industrial energy use per person.

One measure of energy efficiency is energy intensity, the amount of energy used per unit of economic production, generally per dollar of gross national product, adjusted for purchasing power parity. The 1995 industrial energy intensity of the United States, 0.62 W S$1, exceeded the world average of 0.35 W S$1. Figures 3c and Figures 3d show the 10 countries with the highest and 10 ten countries with the lowest industrial energy intensity.

Concerning energy end use, detailed data on a global scale are not gathered. In the United States, however, the Department of Energy does regularly survey energy end use. Americans use approximately 40% of total energy for industrial processes and agriculture. Approximately 33% of energy use goes to cooling, heating, lighting, and maintaining commercial and residential buildings. The remaining 23%, almost all from oil, goes to transportation. Passengers vehicles use half of all transportation energy. The high energy per unit volume and the flexibility of a liquid render petroleum products extremely convenient for powering vehicles.

Globally, a third of energy use goes to electricity generation, mainly from coal, hydroelectric, and nuclear. Power plants release two-thirds of that as waste heat (see the next section). The remaining third mainly goes into the end use of industrial processing with the balance going to cooling, heating, and lighting. Households generally use the traditional energy sources of firewood and charcoal for the end uses of cooking and heating. Generally, cooking a joule of food requires 2 J of firewood wood or 8 J of wood converted to charcoal. Consequently, rural people use 1 to 2 kg wood cap−1 d−1 for a rate of energy use of 250 to 500 W cap−1. Actually, a total of only 20 to 40 W cap−1 actually enters the cooked food and warmed people.
Open fires will diffuse the rest as waste heat (see the next section). In urban areas of nonindustrial countries, people often rely on charcoal for energy. Even though the conversion of wood to charcoal releases waste heat, the end product has higher energy per unit mass than firewood. This makes charcoal easier to store and transport than firewood. Urban people use 100 to 150 kg charcoal cap$^{-1}$ y$^{-1}$, requiring 800 to 1200 kg wood cap$^{-1}$ y$^{-1}$. The ultimate end-use energy requirement is 30 to 45 W cap$^{-1}$.

### II. IMPLICATIONS OF THE LAWS OF THERMODYNAMICS

The first law of thermodynamics states that energy is neither created nor destroyed, only converted between different forms. This is the principle of conservation of energy. The first law means whatever energy a process does not convert into useful forms must still go somewhere. The nonuseful energy does not just disappear. Humans use the environment as the sink for this waste energy.

The second law of thermodynamics states that any system will tend to change toward a condition of increasing disorder and randomness. This is the principle of increasing entropy. The second law means that no energy transformation can convert 100% of one energy form completely into a useful form. The process will always release amounts of energy wasted in forms that are unrecoverable due to the disorderliness or randomness of the waste energy forms. The fewer energy transformations that a system contains, the fewer chances for random second law energy losses.

For example, the objective of an automobile’s internal combustion engine is the conversion of chemical energy in the covalent bonds of hydrocarbons in gasoline to heat energy of an expanding fuel-air mixture in the piston, to kinetic energy of the drive shaft, to kinetic energy of the main axle. No matter how efficient the engine and automobile technology is, the conversion process will always waste energy as heat in the friction of engine parts, sound in the banging of vehicle compo-
neutrons, heat in the friction of tires on the road, kinetic energy of the wind displaced by the vehicle, and countless other unrecoverable losses.

As another example, the objective of a coal-fired electric power plant is the transformation of the chemical energy in the coal to heat energy in the boiler, to heat energy in steam, to kinetic energy of a turbine fan, to electromagnetic energy in the generator coil. Along the way, the conversion processes lose energy as the light and sound of the boiler fire, the vibration of turbine parts, the heat of power plant components, and, most significantly, the waste heat carried by the power plant cooling water.

Theoretically, the maximum efficiency across a heat gradient is the Carnot efficiency:

$$\eta = 1 - \frac{\text{Temperature of heat sink}}{\text{Temperature of transformation}}$$

with temperatures in Kelvin.

For a coal-fired power plant, materials limit boiler temperatures to 1000 to 1200 K. At an ambient environmental temperature of 293 K, the maximum efficiency will be 70 to 73%. Typically, coal plants only achieve 30 to 35%, releasing two-thirds of the total as waste heat.

Table II gives various formulations of the first and second laws of thermodynamics. The inevitability of entropy losses makes the colloquial interpretation of the second law “You can’t even break even.”

III. BIODIVERSITY IMPACTS OF INDUSTRIAL ENERGY

A. Oil

The major impacts of oil on biodiversity derive from a fuel and use cycle that ranges over vast areas of terrestrial and marine habitat. Exploration, drilling, crude oil transport, refining, and utilization in vehicles change land use and introduce industrial pollution to land and sea.

Petroleum, or oil, consists of a complex mixture of hydrocarbons formed over geologic time from organic matter compressed under anoxic conditions. The most important chemical constituents are alkanes such as octane and methane and aromatics such as benzene and toluene.

The majority of oil deposits derive from aquatic plants and bacteria deposited in inland seas and coastal basins during the Cretaceous Period 100 million years ago. In the early stages of formation, bacteria initiated the anoxic reduction of the organic matter. Over time, pressure and temperature replaced microbial activity as the main agent of transformation. Eventually, these forces drove off most of the water, oxygen, and nitrogen from the condensate, leaving carbon and hydrogen compounds. Dispersed between sediment granules, the oil eventually migrated to low pressure geologic traps at depths of 1 to 7 km. Today, oil fields occur at an average depth of 1.5 km. On average, the stoichiometric composition of crude oil is CH₁.₅, with a very small amount of sulfur.

Petroleum exploration entails geologic surveys over extensive areas often with low human populations and relatively undisturbed natural communities. Exploratory surveys generate vehicle traffic and temporary dwellings that bring localized disturbances, but the most serious impacts occur with seismic detection. This method involves controlled detonations along lines or at points so that seismometers can extrapolate the layout of subsurface formations. These activities destroy areas of vegetation, disturb certain animals, especially ground-nesting birds, and fragment habitat. If such activities disturb animal behavior during breeding times, the impact can last over many growth periods.

Edwin L. Drake drilled the world’s first commercial oil well in Titusville, Pennsylvania, in 1859. All oil wells require access roads, and high-volume wells require buildings and electric and water lines. This infrastructure destroys vegetation and takes land away from animal habitat. The more extensive an exploited oil field, the wider the habitat impacts extend. Infrastructure at the Prudhoe Bay field, opened for drilling in 1968, now extends over 1700 km² of Arctic tundra. This has noticeably displaced calving of Rangifer tarandus (caribou) from the field. Likewise, proposed exploitation of Area 1002 in the Arctic National Wildlife Refuge would disrupt the migration routes of the porcupine caribou herd to its calving grounds.
Drilling operations produce water and air pollution. Serious water pollution comes from the vast amount of used drilling muds, which are lubricating substances pumped down to the drilling bit to carry away rock cuttings, to keep the bit from overheating, and to protect the drilling shaft from surrounding rock. Drilling muds consist of water mixed with light molecular weight oils. Used muds contain bits of metal from drilling components and any trace metals mobilized out of the drilled rock.

All stages of the oil production system from drilling operations to end use spill oil into surface and ground waters. Globally, oil spills into surface waters total more than 3 million tons each year. Half of these spills come from oil production, 40% come from nonpoint urban runoff, and the remaining come from natural seeps. At the start, spills occur at well blowouts when equipment fails to contain naturally high fluid pressures in oil-bearing strata. Spills also occur along the significant lengths of pipeline from the wellhead to tank farms to supertanker ports to refineries to gas stations. Pipes, valves, and tanks leak from fatigue and from human error.

These and other problems roused concern when oil companies first proposed construction of the Trans-Alaska pipeline to carry crude oil 1300 km from the North Slope to the Gulf of Alaska. When it eventually started operations on June 20, 1977, the Trans-Alaska pipeline integrated a set of environmental protection features. To prevent thawing of permafrost areas, brackets elevate 700 km of pipeline to heights of 3 m. Heat pipes at the bracket legs dissipate heat generated by the friction of oil passing through the pipe.

The elevated sections serve as underpasses for caribou. Over buried sections in certain permafrost areas, construction engineers designed refrigerated overpasses for caribou. Bridges carry the pipeline over 800 streams. Zigzags along the pipeline translate longitudinal movement of pipes expanding under heat to lateral movement, reducing the risk of leakage. Oil companies revegetated areas denuded by construction activities.

An access road now open to the public parallels the entire length of the pipeline. This road has opened up a strip of habitat to human contact, possibly changing behaviors among caribou and other mammals.

On March 24, 1989, the supertanker Exxon Valdez ran aground on Bligh Reef in Prince William Sound in the Gulf of Alaska, ruptured, and poured out 41 million liters of crude oil, the largest oil spill ever in U.S. waters. The spill caused acute damage to birds, marine mammals, and intertidal communities. The spill also caused chronic damage to fish species and intertidal and subtidal communities. The progression of the spill demonstrates a pattern repeated in smaller spills that occur frequently in the world’s shipping lanes.

Oil floats on top of water. Gravity and wind will spread a floating slick out to a thickness of 0.3 to 10 μm. Patches 0.1 to 5 mm thick can cover just 10% of the total slick area yet contain 90% of the total slick volume. Some oil dissolves and emulsifies into the water column, forming emulsions containing 80% H2O. Oil generally will not sink to depths below 20 m. In the Exxon Valdez spill, recovery teams deployed an array of countermeasures that included booms, skimmers, sorbents, pumps, burning, and surfactants for chemical dispersion.

Exposure to sunlight initiates photolysis of hydrocarbons into lighter molecular weight compounds. Heterotrophic bacteria will also oxidize hydrocarbons to smaller compounds, CO2, and water. The lightest hydrocarbons, as well as aromatic compounds such as benzene, volatilize. Loss of the lighter fraction leaves the remaining slick more viscous over time. This thick oil forms tar balls and pancake-like forms. Oil from the Exxon Valdez eventually spread across hundreds of kilometers of beaches, penetrating deeply into cobbled stretches and mussel beds. Today, oil still persists beneath the surface layer of rocks in many areas.

Three years after the Exxon Valdez spill, photolysis degraded 70% of the original oil. Bacteria then eliminated photolysis products amounting to 50% of the original crude oil; the other 20% evaporated. Work crews recovered 14% of the spill. Thirteen percent of the original oil sank into subtidal sediments. Beaches absorbed 2%, leaving 1% still suspended in the water column.

The spill occurred in early spring, just before the young of many species emerged to rejuvenate marine animal populations. C. pallasi (Pacific herring) were spawning inshore. Millions of O. hermaphroditus (pink salmon) fry were soon to be washed from gravel spawning beds into the spring plankton bloom offshore. P. vitulina (harbor seal) and Enhydra lutris (sea otter) pups were testing the frigid waters. Seabirds were beginning to converge on breeding colonies in the gulf. Consequently, the oil devastated populations of birds, marine mammals, and fish.

Thousands of birds can die in even moderate spills, but the Exxon Valdez spill eventually killed more than a quarter of a million birds of more than 90 species, the greatest demonstrated mortality of birds from any oil spill. Workers physically recovered 36,000 carcasses. Of these, 8000 were Brachyramphus marmoratus (mar-
bled murrelets) and 150 were Haliaeetus leucocephalus (bald eagles). The spill killed individuals of two Fratercula spp. (puffins) and four Uria spp. (loons). For the following three years, fewer breeding Uria aalge (common murre) showed up at spring colonies.

Oil coats feathers, matting and waterlogging them. The water repellency, buoyancy, and insulating properties of plumage derive from a precise, orderly arrangement of feather barbules and barbicelles. Contact with oil disrupts these arrangements. Soaked birds can die of hypothermia and drowning. Those that survive risk chronic exposure to toxic organic compounds through ingestion, inhalation of fumes, or absorption. Moreover, eggs are highly sensitive to contact with oil.

Many of the aromatics in petroleum, including benzene, toluene, xylene, and phenols, are lethal to animals on contact and carcinogenic under chronic exposure. Moreover, polycyclic aromatic hydrocarbons bond to lipophilic sites, an affinity that magnifies these compounds up the food chain. Even when not deadly, sublethal disruption of physiology or behavior activities can reduce resistance to infection and cause generalized stress.

In the wake of the Exxon Valdez spill, 300 of the 2200 harbor seals in Prince William Sound died, as well as 3500 to 5000 out of 10,000 sea otters. Like birds, oil obliterates the insulating properties of marine mammal pelage, leaving them to die of hypothermia. In addition, oil can clog the nostrils of seals, causing them to suffocate. Whales, insulated not by hair, but by layers of oily blubber, resist the effects of oil, although a well oiled whale can clog its nostrils for hours. In Prince William Sound, harbor seals may experience chronic problems because oil is accumulating in their bile and fatty tissues. Since the spill, sea otters have continued to experience elevated mortality.

An unfortunate coincidence has resulted in the geographic juxtaposition of important commercial fisheries and high yield offshore oil fields on the continental shelves. Not only do oil spills invariably cause fish kills, but chronic effects also reduce fish fitness years after initial exposures.

Oil at the air-water interface acts as a physical barrier interfering with gas exchange. In fact, oil has been a traditional line of defense used for mosquito larvae control. Under a thick slick, fish larvae can suffocate. Fish eggs, which often float at the sea surface, and fish larvae, which are often distributed in the upper water column, both occur in the areas of highest oil concentration. Hydrocarbons and aromatics damage eggs on contact. Oil concentrations will quickly exceed the LC₅₀ of 1 to 10 ppm for fish larvae. The early life stages of intertidally spawning fish are especially susceptible.

Exposure to toxics from the Exxon Valdez spill has caused chronic problems in Clupea pallasi (Pacific herring), Oncorhynchus clarki (cutthroat trout), Oncorhynchus gorbuscha (pink salmon), and Salvelinus malma (Dolly Varden). Fish species have shown elevated egg, larvae, and adult mortality, larval deformities, and poor adult growth rates, even in situations of constant food supply. Fish tissues in some species contain elevated concentrations of toxics.

Over time, tidal action spreads and coats the shore of the intertidal zone in a band of oil. This oil ring smother intertidal invertebrates, crustaceans, mussels, barnacles, limpets, and algae. Oil coatings will asphyxiate filter feeders. Recovery crews use hot water washes to clean oil coated shores, an effective method, yet destructive to intertidal organisms.

Oil spills also damage phytoplankton and other marine plants. Oil absorbs photosynthetically active radiation, so direct coating hinders plant growth and increases plant tissue temperatures. Aromatics may disrupt the orderly arrangement of grana in chloroplasts. An increase in ruderals characterizes the changes in plant species diversity. Blue-green algae blooms will increase eutrophic conditions.

Oil refining focuses on the catalytic cracking of carbon-carbon bonds of long-chain alkanes for the production of lower molecular weight hydrocarbons. Refiners try to recover every possible useful organic compound, from the light products methane, benzene, toluene, and kerosene, to medium-weight products like gasoline and diesel fuel, to heavy tars and asphalt. These processes, as well as sulfur recovery, inevitably generate water pollution.

Most constituents of petroleum and refined oil products volatilize easily. Consequently, each step of the petroleum fuel cycle generates air pollution. Methane, ethane, benzene, toluene, and other compounds will evaporate from crude oil exposed to air. The major emissions from oil refineries include CH₄, CO, CO₂, H₂S, NOₓ, and SO₂.

This section has concentrated on the impacts from the core stages of the petroleum fuel cycle: exploration, extraction, transport, and refining. Nevertheless, manufacture of the infrastructure and materials needed for these end uses generates industrial pollution and requires land. Moreover, armed conflicts caused, in part, by efforts to control access to oil fields and refineries take human life and directly disrupt ecosystems.

The combustion of refined oil products for transpor-
B. Natural Gas

Natural gas is a mixture of light hydrocarbons that exists at a gaseous state at standard temperature and pressure. Methane (CH₄) is the main constituent, but the presence of higher molecular weight alkanes, including ethane, propane, and butane, changes the average stoichiometric composition for natural gas with the water vapor removed to 0.79 CH₃.62. Formed by the same processes that formed oil, natural gas is often found at the top of oil deposits. The most voluminous natural gas reservoirs occur in Cretaceous strata. The land use changes brought by the exploration and extraction of natural gas produce the same biodiversity impacts as described for oil.

In the nineteenth century, companies had not yet erected natural gas pipelines or processing facilities. Moreover, industry had not yet developed much technology for using natural gas. Because companies found natural gas uneconomical to exploit, they just burned it off to reduce the risk of fire and explosion. The entire history of natural gas production has flared the equivalent of 8 years worth of U.S. energy use. Today, U.S. companies generally flare only small amounts at refineries, but companies from other countries flare enough that the total amount flared amounts to 5% of global natural gas production.

Gas companies generally pump natural gas straight from the well to a processing plant, eliminating the need for storage facilities at the wellhead and thus reducing the potential for leakage. Gas companies generally divide natural gas into three fractions: natural gas liquids (NGL), liquefied petroleum gas (LPG), and liquefied natural gas (LNG). NGL consists of the higher molecular weight fraction of natural gas that often settles out by gravity. Processing of natural gas from oil wells produces liquefied petroleum gas (LPG). Finally, pressurization of natural gas produces liquefied natural gas (LNG), a product that is expensive because of the special containers required for transport.

The major end uses of natural gas, cooking and heating, burn the fuel directly with no further transformation. Electricity generation from natural gas uses a gas turbine, which directly uses the hot gas products of combustion to turn the turbine fan, eliminating the intermediate step of steam generation used in oil and coal-fired plants. Cogeneration plants increase the energy efficiency of gas turbine systems by utilizing the waste heat of gas turbines for space heating or industrial processes.

The extraction and combustion of natural gas pollute much less than the extraction and combustion of oil. Because it exists in the gaseous state for much of the fuel cycle, natural gas exploitation does not produce significant amounts of water pollution. However, methane itself is a greenhouse gas, and its combustion produces the main greenhouse gas, CO₂.

C. Coal

Coal consists of hard carbonaceous material formed by the compression and transformation of terrestrial plant matter rich in cellulose buried at the bottom of ancient freshwater swamps and bogs. The richest coal-bearing strata date from the Cretaceous period 100 to 200 million years ago and from the Permian period 250 million years ago. Similar to the process of petroleum formation, the deposited plant matter undergoes incomplete decay in anoxic conditions.

In geologic time, the pressure of overlying rock and the temperatures generated therein drive off oxygen and hydrogen, leaving thick seams of reduced carbonaceous rock containing much more organic than mineral matter. The average stoichiometric equation of coal is 0.75CH₄0.8, but elemental sulfur also contaminates most coal deposits. The four major types of coal, in order of decreasing carbon content and increasing sulfur, are anthracite, bituminous, subbituminous, and lignite. Bituminous coal is the most physically abundant type worldwide. Peat, the partially oxidized, moist, organic soil that forms in marshes and bogs, is the very early precursor to coal. In certain areas, people burn peat for heating, cooking, and light.

The coal fuel cycle extends from extraction at the mine to conversion at a power plant to distribution across the electric grid to end uses in lighting, heating, and all the uses of electricity.

Coal mines generally fall into three types: deep, open pit, and strip. Deep mines extend down to a depth of around 1 km. Open pit mines reach down to 300 m. Strip mining generally removes the upper 30 m of land surface. Coal mines consume land, not just for areas actually excavated and areas used to dump unwanted extracted rock, but also for the support infrastructure of buildings, roads, and rail lines.

Deep and open pit mines remove huge amounts of rock, termed overburden, lying over the coal. The land over deep mines will sink, a process termed subsidence, drastically changing the topography, hydrology, and
Miners dump the huge amounts of unwanted extracted rock, termed mine tailings, in abandoned parts of active mines or on the surface. Pyrite (FeS₂) usually comprises a significant fraction of the tailings. In addition to being poisonous to plant and animal life, sulfurous acid mobilizes other toxic substances. The leaching of acids, trace metals, dissolved solids, and toxic organics produces a brew known as acid mine drainage that can devastate surface waters. Selenium and cadmium often occur in high concentrations in tailings, so acid mine drainage can initiate the bioaccumulation and bioconcentration of these trace metals in the surviving sections of the food chain.

Surface mining consumes vast tracts of land. Heavy machinery remove the upper layer of a landscape to expose relatively shallow coal seams, completely destroying the mined area. Although coal companies generally fill back the overburden into the mined area and replant it, strip-mined land never recovers its original characteristics. Replanting even creates opportunities for ruderals to expand where perennial plant species may have dominated. Rodents and other animals that adapt readily to human disturbance also take advantage of reclaimed areas.

Coal mines often need to impound surface streams to satisfy the significant water needs of mine operations. These needs include water cannon drilling, transport by slurry, fugitive dust spraying, coal washing, and size sorting. Mines crush and screen coal for uniform sizing, then wash and dry the coal for open air storage. The fugitive emissions from these processes consist of particulates that coat any exposed surface, blocking photosynthetically active radiation from plants, contaminating food and water sources for animals, and acidiying affected soil. Leaching of toxic substances from coal storage piles can also add to the pollution of surface waters. Rail transport provides the most cost-effective means of moving the bulky commodity of coal. Fugitive emissions from unit trains increase the particulate load in rail corridors. To save money on rail transport, many utilities will site electric power plants next to the mine to wire out the electricity. In certain regions, this shifts the pollutant load from urban areas to less polluted rural areas.

Most coal worldwide goes to electricity generation. A conventional power plant burns coal in a boiler to boil water that circulates through a closed loop system of pipes. The steam from the boiler enters a steam turbine to turn huge fans that power an electric generator that converts kinetic energy to electric energy. As a principal of physics, the movement of a conductor across a magnetic field creates electric current in the conductor. In the coal-fired power plant electric generator, the conductor consists of stationary coils of wire surrounding a magnet on a shaft rotated by the turbine fan. Much of the steam that moves through the fan transfers its heat energy to the kinetic energy of the fan, causing the steam to condense back to water. A condenser will then allow heat to transfer from any steam that continues past the turbine to an external supply of cold water. The water in the internal loop from the condenser returns back to the boiler to enter the steam cycle again.

Coal combustion releases CO₂, CO₂, SO₂, NOₓ, particulates, fly ash, arsenic, cadmium, chromium, mercury, and selenium. Nearly 40% of anthropogenic CO₂ emissions come from burning coal, whereas coal burning produces 80% of human SO₂ emissions. Consequently, greenhouse gases and acid precipitation may constitute the agents of coal's most extensive environmental effects. The slag remaining from coal burned in the boiler contains high amounts of trace metals, especially cadmium and mercury. In addition, the sludge from flue gas desulfurization units, the pollution control devices known as scrubbers, contains trace metals and toxic organics. The disposal of this sludge presents problems for land use and water quality.

Internal steam turbine water is the working fluid circulating from the boiler to the turbine to the condenser and back to the boiler. Cooling water is the medium that draws heat from the internal steam turbine water. In most conventional coal-fired power plants, the internal steam turbine water remains separate from power plant cooling water. A typical condenser consists of copper coils, carrying cooling water, that pass through larger structures carrying the internal steam turbine water. As a physical principle, heat passes from the steam turbine water through the walls of the copper coils into the cooling water.

A 1 GW coal-fired power plant typically requires 4 million m³ per day for all operations, mostly for cooling. These water needs dictate the necessity to locate a plant next to a natural water body. Power plants mainly use fresh water because of the corrosive effects of salt water. Water withdrawals change the hydrology of a watershed, changing water levels, surface area of mudflats,
surface area of wetlands, and other important habitat characteristics that can strand hydrophilic plant species such as Salix spp. (willows) and harm fish and shorebird populations. Impingement on intake screens kills significant numbers of fish and other aquatic species. Organisms that get through the screens undergo entrainment through the condenser, causing even greater mortality. The stress that any surviving organisms undergo reduces their fitness considerably.

All power plants, including coal, oil, and nuclear, generate three-quarters of the waste heat dumped into U.S. surface waters and into the atmosphere above the United States. Once-through systems dump the waste heat directly into local waters. Cooling towers dump waste heat into the atmosphere, condensing steam from the air. Cooling ponds provide a buffer for releasing some of the heat from cooling water into the atmosphere, reducing the temperature of the cooling water before it enters surface waters.

Thermal discharges into freshwater and coastal zones cause a host of negative effects on aquatic species:

1. Direct lethality to fish and crustaceans at water temperatures >35°C.
2. Decrease in dissolved oxygen.
3. Increase in metabolic rates and nutrition needs for fish and changes in nutrition requirements for other taxa.
4. Displacement of diatoms by green and blue-green algae.
5. Inhibition of vertical migratory behavior by zooplankton.
6. Thermal plume blockage of migratory fish movement.
7. Avoidance of warm areas by migratory waterfowl.
8. Early emergence of aquatic insect adult life stages into inhospitable environmental conditions.
9. Copper contamination from condenser coils.

Long-range transmission of electricity occurs across high-voltage lines strung on metal towers up to 30 m tall. The 115 kV network in the United States stretches across 200,000 km and occupies 2 million ha. The clear cutting of corridors 30 to 60 m wide for transmission easements directly changes the vegetation and plant life in cut areas. Periodic clearing maintains and intensifies the original changes. The areas that remain favor ruderals and animal species that adapt readily to human disturbance, such as Odocoileus virginianus (white-tailed deer). Herbicides used for periodic clearing can harm insect and bird species. Transmission line corridors fragment habitat and increase the area of habitat susceptible to edge effects. The cleared areas can also block migrating land animals.

Short-range electricity transmission occurs across low-voltage lines strung on wood, metal, or concrete poles generally 5 m tall. Harvesting wood poles can produce all the potential biodiversity impacts of commercial logging, monospecic plantations, and milling. In many countries, utilities treat the wood with creosote to guard against the action of insects and weather. Creosote, a by-product of crude oil refining, contains significant amounts of toxic organics that can leach and contaminate surface waters.

The material and energy needs for building the massive infrastructure of the coal fuel cycle produce wide-ranging environmental effects. Because most coal goes to electricity generation, the end uses of coal produce the environmental effects associated with climate control, lighting, commercial production machinery, residential appliances, and other electric devices.

D. Nuclear Fission

Nuclear fission is the splitting of high molecular weight elements to release energy held among protons and neutrons in the nucleus of the atom. Uranium and plutonium are the elements that provide the most effective yield from fission at current levels of technology. A fission reaction produces energy in the form of light, heat, motion of the split pieces, and radiation. Radiation consists of kinetic energy of small molecules and atomic particles and electromagnetic energy of photons traveling at certain frequencies. When radiation passes through living tissue, the particles or photons impart their energy to atoms and molecules in the tissue, disrupting molecular and atomic structures.

The fission products themselves will continue to emit radiation until they reach a stable atomic state. Strontium-90 and Cesium-137 have half-lives of decades, but Plutonium-239 decays with a half-life of 25,000 y and Iodine-129 will halve in mass only after 17 million years.

Nuclear fission plants require highly processed uranium fuel. A 1 GW fission plant requires 150,000 Mt UO₂-containing ore to fabricate enough fuel for one year. Milling this removes 150 Mt UO₂. In order to concentrate Uranium-235, a conversion plant converts UO₂ to 188 Mt of UF₆ gas. Differential diffusion of the UF₆ separates 31 Mt UF₆ enriched in Uranium-235. A fuel fabrication plant then produces 30 Mt of UO₂ pellets.

The mining and milling of uranium ore creates most of the same environmental problems already described
for deep mining for coal and for coal processing. Conversion, enrichment, and fuel fabrication require fluo-
rescent gas, which is lethal on contact to animals, damages vegetation, and reacts to form toxic by-products.

According to the International Atomic Energy Agency (IAEA), at the end of 1998, 334 nuclear fusion
plants were operating in 33 countries around the world; 104 nuclear fission plants were operational in the
United States. These plants possessed a combined rated capacity of 349 GW and generated 2300 TWy of elec-
tricity, 16% of the world total. Plant operating experi-
ence reached 9000 plant years.

Nuclear plants generate electricity in a steam cycle very close to that employed in coal plants, except that
nuclear fission provides heat to the boiler. The higher operating temperatures require more cooling water than
a coal-fired plant of the same electric generation capac-
ity. A 3 GW nuclear fission plant requires 6 million m³
of cooling water each day, so the effects of water intake
and thermal discharge described in the previous coal
section are all more serious for nuclear plants.

Because nuclear plants involve combustion only in
construction and in support vehicles for operations,
they produce few air emissions. Nuclear plants do, how-
ever, produce long-lived radioactive wastes. Low-level
wastes include reactor containment water, worker

clothing, exposed tools, and plant fixtures irradiated
and in a steam explosion. The explosion destroyed the
instantaneous catastrophic increase of thermal power
RBMK graphite moderated reactor resulted in a virtually
principal effects of hydroelectric plants come from the
total physical and hydrologic alteration and partial in-
undation of a watershed. Besides the forced removal of
people and inundation of homes, hydroelectric plants
also cause significant ecological changes.

More than 40,000 large dams now straddle rivers
around the world, creating reservoirs that inundate
more than 400,000 km². The Akasambo Dam on the
Volta River in Ghana created the largest impoundment
in the world, covering 8500 km². The Three Gorges
through the year 2080. The Soviet government evacu-
ated all people from a zone of 30 km radius and con-
structed a cement sarcophagus to contain the remains
of the reactor core.

Lethal radiation killed many conifers and small
mammals within 10 km of the accident in the first few
weeks, but populations have since mostly recovered.
By 1998, radioactive decay had diminished the amount
of radioactive materials in the immediate area to 1% of
their original amount, mainly as Cesium-137 in topsoil.
Trees have accumulated Cesium-137 in growth rings.
Grass, mushrooms, and berries also continue to incor-
porate the isotope, perpetuating a source of exposure
for species that feed on contaminated plants. Aquatic
ecosystems have generally tolerated the radioactivity
concentrating in sediments, although fish may be accu-
mutating radionuclides.

Ecologists have still not determined the long-term
genetic effects of the fallout from Chernobyl. Appar-
ently, the accident did not eliminate any plant or animal
species, except where cleanup activities involved soil
removal. Indeed, as a result of the evacuation, some
plant and animal populations have thrived.

From 1961 to 1976, ecologists, led by George M.
Woodwell, examined the chronic effects of irradiating a
forest at Brookhaven, New York. Gamma radiation
from Cesium-137 caused sensitive species to die, allowing resistant species and ruderals to invade. Spe-
cies richness in 2 m square plots fell by half.

E. Hydroelectric

Hydroelectric systems harness the potential energy rep-
resented by an elevated mass. The potential energy of
water at elevation will convert to increased kinetic en-
ergy of the water when the water runs to a lower eleva-
tion. A dam concentrates the difference in elevation,
termed hydraulic head, in a spillway equipped with a
turbine and electric generator. The electricity produced
immediately enters the electric grid. In this manner, a
hydroelectric plant will generate electricity with few
direct air emissions and little thermal discharge. The
principal effects of hydroelectric plants come from the
total physical and hydrologic alteration and partial in-
undation of a watershed. Besides the forced removal of
people and inundation of homes, hydroelectric plants
also cause significant ecological changes.

More than 40,000 large dams now straddle rivers
around the world, creating reservoirs that inundate
Dam under construction in the People's Republic of China will be the hydroelectric plant with the highest generation capacity in the world, 18.2 GW. The project, under construction in the period 1993–2009, will flood 1100 km² along 600 km of the world’s third longest river, the Yangtze, and displace 1.2 million people. The dam will require 26 million m³ of concrete.

The inundation of formerly dry land submerges vegetation and immediately decreases the area of animal habitat. Lost forests represent ecosystem services and biomass wasted to decomposition. In Brazil, a country that depends on hydroelectric for 20% of its industrial energy, the land requirement for hydroelectric reservoirs averages 450 km² GW⁻¹ with a range of 17 to 10,000 km² GW⁻¹.

A dam blocks nutrient-rich sediment that a river system otherwise would have deposited in floodplains, wetlands, and at the outlet delta. Not only does the sediment buildup fill in a reservoir and eventually impair electricity generation, but the blocked sediment also represents a source of organic carbon and other nutrients wasted at the bottom of the reservoir. As the delta, bay and estuary topography changes, mudflat areas decrease, and nutrient-rich upwellings can decline. The Aswan High Dam blocks 98% of the 120 million tons of sediment that the Nile had carried to the sea each year, formerly depositing 10 million tons on the floodplain and delta. Consequently, soil depth has thinned and agricultural production has declined in the Nile Valley. Blockage of sediment and fresh water by the Akosombo Dam in Ghana has caused the decline of clam populations in the Volta estuary, and populations of Sphyraena barracuda (barracuda) offshore in the Gulf of Guinea. In addition, coasts become more susceptible to erosion.

Utilities start and stop the flow of water based on electricity and operational requirements. One operational objective is to smooth out natural extremes in the flood regime. This will usually change the meandering response and other channeling processes of a river. Ever since the Glen Canyon Dam removed spring floods in the near downstream section of the Colorado River, sandbar erosion has increased because the river does not flow fast or deep enough to move the amount of silt required for extensive sandbar formation. The resulting disappearance of some riparian tree species has led to the decline of Empidonax trailli (Southwestern willow flycatcher) and other birds. To mitigate the problem, the U.S. Department of the Interior staged a controlled flood in 1996.

For some dammed rivers, the flow of water unburdened by silt can deepen the riverbed. This lowers the water table of surrounding land. Also, the depletion of riverbed gravel can harm any species of fish, insect, mollusk, or crustacean that requires gravel bottoms to spawn. Many insect, amphibian, and fish species also use gravel areas for habitat or for protection.

The depth of a reservoir will often keep water at a temperature lower than that in the native river. For example, the Glen Canyon Dam changed the water temperature in the near downstream section of the Colorado River from a range of 0 to 27°C to a relatively constant 8°C. This has been a major factor in the extinction of Ptychocheius huctus (Colorado squawfish), Gila robusta (roundtail chub), and Gila elegans (bonytail chub) and in the endangerment of five other fish species. Whereas the release water is clear, reservoir water often becomes slightly eutrophic and turbid. This degraded water quality can harm certain species.

The impacts of dams on anadromous fish relate to the migratory behavior and timing of the life cycles of these unique species. Dams render hazardous the downstream migration of young fish and block the upstream migration of adults. Moreover, salinity and temperature adaptations occur on a precise schedule, making long delays lethal. Disoriented and fatigued fish more easily fall prey to predation. Despite the deployment of extraordinary means in contemporary times to facilitate fish migration, including fish ladders, elevators, and trap and haul trucking, dams have eliminated anadromous species from many rivers. Runs of Salmo salar (Atlantic Salmon) and Alosa sapidissima (American shad) have disappeared from many rivers in the Northeast United States. In the Columbia River Basin in the Northwest United States, overfishing, pesticide runoff, and hydroelectric plants have endangered populations of Oncorhynchus nerka (Snake River sockeye salmon) and Oncorhynchus tschawytscha (Snake River chinook salmon). The physical barrier formed by a dam can even divide populations of aquatic species, altering patterns of gene flow and genetic variation.

Exotic fish species adapted to human disturbance and introduced into reservoirs for sport fishing will often outcompete native species. In the 1350 km² reservoir straddling the Brazil–Paraguay border behind the Itaipu Dam—with a generation capacity of 12.6 GW that currently ranks it the highest in the world—a non-native species, Plagioscion squamosissimus (curvina) has become the second most numerous species. PCBs released from circuit breakers and oil leaking from machinery constitute the worst direct industrial pollution from dams. These and toxic organics build up in sediments and magnify up through the food chain. Impingement of aquatic organisms on intake screens...
The material and energy needs for building the massive infrastructure of the hydroelectric energy cycle produces wide-ranging environmental effects. The end uses of hydroelectricity will produce the environmental effects associated with climate control, lighting, commercial production machinery, residential appliances, and other electric devices. Because smelting aluminum from bauxite ore requires a large amount of electricity, aluminum smelting comprises an end use closely tied to the hydroelectric option. The air emissions from smelters include CO, CO₂, particulates, NOₓ, and trace metals. Major water emissions include trace metals and sulfates.

F. Renewable Energy Technologies

Renewable energy includes those forms of energy whose transformation does not necessarily consume the ultimate source of the energy, harnessing instead solar radiation, wind, the motion of water, or geologic heat. This section covers renewable energy technologies, including solar heating, solar thermal electric, solar photovoltaics, electric wind turbines, biomass-to-electricity conversion, biomass-to-alcohol fuels, and geothermal electric. These are renewable energy systems that depend on complex technology, so they are forms of industrial energy. The following section on traditional energy covers the simpler forms of renewable energy—firewood and charcoal.

Renewable energy forms share the physical characteristics of site specificity, variable availability, diffuse flow, and low or no fuel costs. Except for biomass-to-electricity conversion, renewable energy technologies do not involve combustion, so they do not directly produce much air pollution. The major environmental impacts derive from the fabrication, installation, and maintenance of renewable energy devices.

Solar energy systems fall into the categories of passive and active. Passive solar technologies consist of architectural forms that more effectively follow the diurnal and seasonal patterns of sunlight for the efficient heating and cooling of a building. Passive systems use the natural phenomena of radiation and convection. On the other hand, active systems use moving devices to achieve heat transfer. The simplest active systems use pipes or other collectors to heat water for residential or commercial use. For the most part, solar heating is environmentally benign.

Solar thermal uses arrays of reflective collectors to focus sunlight on a water boiler for the turbine production of electricity. These systems require significant amounts of land for the parabolic or trough collectors. Because solar is generally economically feasible only in hot sunny areas, sites are generally arid and water is scarce. Water withdrawals for the turbine and for washing the collectors can damage aquatic ecosystems. The bright arrays can also harm birds. Photovoltaics are solid-state devices in which photons stimulate the emission of electrons and semiconductor materials channel the electrons for collection. In this way, photovoltaics directly convert sunlight to electricity with no moving parts, except for devices that move photovoltaics to track the sun, and no water, except for water to occasionally wash photovoltaic surfaces.

The fabrication of photovoltaic (PV) cells produces noxious environmental impacts. The first step is mining the quartz that constitutes the base material of a PV cell, so this produces many of the impacts on aquatic and terrestrial biodiversity described for coal mining. Then the production of metallurgical grade silicon requires the refining of quartz to 99% purity at 3000°C in an electric arc furnace. The production of semiconductor grade silicon occurs through a fluidized bed reaction of the silicon with hydrochloric acid. Then the production of semiconductor grade polycrystalline silicon occurs by electrically heating at 1000°C the semiconductor-grade silicon for vapor deposition on a silicone substrate. Remelting the polycrystalline silicon produces a form that can grow into crystals. These crystals are sawed into wafers 0.5 mm thick, wired, and encapsulated in glass 3 mm thick.

Trace metals are used to dope the semiconductor for the principal types of photovoltaic cells, including gallium arsenide, copper indium diselenide, cadmium telluride, indium phosphide, and cadmium sulfide. The trace metals, together with chlorinated organic solvents and phosgene gas, produce hazardous air, water, and solid wastes that can be lethal on contact or carcinogenic in small doses. The conversion of biomass into electricity involves burning specially grown wood or crops in low pressure boilers to power steam turbines or the gasification of organic matter into methane to power gas turbines. The United States currently possesses a biomass electricity-generating capacity of 7.6 GW. Biomass-for-energy plants in the United States often employ cogeneration to provide process heat for an adjacent industrial facility. The principal species used include short rotation trees Populus spp. (poplars, aspen, cottonwoods), Plat-anus spp. (sycamore), and Acer saccharinum (silver maple) grown at densities of 1600 to 5000 trees ha⁻¹. Herbaceous energy crops include Panicum virgatum
(switchgrass) and Andropogon gerardii (big bluestem). Brazil generates electricity and cogenerates heat from the organic wastes, or bagasse, left from the processing of sugarcane and orange juice.

The environmental impact of an energy crop depends on the previous land use as well as the cultivation techniques of both the new crop and any previous old crops. An energy crop can generate negative effects on biodiversity if it is grown in monoculture, if it is grown using pesticides, and if vegetation is clear-cut to prepare for the energy crop. Still, if previous land-uses were less environmentally sound than the energy crop, then the energy crop constitutes a mitigating practice. Previous sections detail the negative biodiversity effects of electric turbines and condensers.

The conversion of biomass into alcohol fuels also requires the dedicated growing of energy crops. Fermentation of cellulose and other complex carbohydrates produces ethanol, which certain engines can burn straight or mixed with gasoline. The United States now produces 4 billion liters of ethanol annually, mainly from corn. Brazil produces enough ethanol from sugarcane to provide for 10% of the country’s energy use.

Otto Cycle engines burn neat ethanol, a mixture of 96% ethanol and 4% water. Modified conventional automobile engines can burn gasohol, a mixture of 78% gasoline and 22% ethanol. At one time, half of the automobiles in Brazil ran on gasohol, the other half on ethanol. Because the combustion of ethanol mainly produces CO₂ and water, with much smaller amounts of hydrocarbons and NOₓ than gasoline combustion, ethanol used for transportation mitigates the most harmful direct effects of petroleum.

For centuries, society has captured wind for moving sailing ships, pumping water, and milling grain. Contemporary wind turbines also power electric generators. Rated at 100 to 300 kW per wind turbine, the steel machines reach heights of 10 m with pinwheel diameters up to 7 m. Arranged in arrays of up to hundreds of turbines, wind “farms” occupy considerable land areas. The greatest arrays cover unique areas in the Altamont Pass in the San Francisco Bay Area in California, the Tehachapi Pass in Southern California, in the Netherlands, and Denmark. Wind farms fragment terrestrial habitats and access road networks cause soil erosion. Spinning turbines can also kill birds.

Geothermal energy captures the heat of hot geologic formations, generating more than 7 GW of electricity worldwide. Geothermal plants sink pipes down to either capture deep hot water or to inject water for it to boil on contact with hot rocks. This process mobilizes trace metals contained in certain geologic strata and releases H₂S gas associated with geothermal deposits.

### IV. BIODIVERSITY IMPACTS OF TRADITIONAL ENERGY

The most important sources of traditional energy are firewood and charcoal, which is produced from firewood. Local people harvest firewood either by coppicing, or cutting at the base, moderately sized shrubs, by lopping branches off mature trees, or only rarely by felling whole trees and splitting the logs.

In semiarid areas of Africa, women prefer the straight, moderately sized branches that only coppiced shrubs produce. Each year, women and, sometimes, their husbands or fathers go out in the dry season and cut at the base shrubs mainly in the family Combretaceae, carry the branches back to the village, and let them dry out. Just before the first rains, men and women cut a store of firewood for the rainy season. This serves, first, to avoid cutting wood that is wet and difficult to burn and, second, to get a time-consuming and strenuous chore out of the way before the exhausting and rushed rainy season. Coppiced shrubs will resprout in the rainy season and, in a year, regrow a full set of branches. When shrubs become scarce, women begin to pull down branches from adult trees, sometimes using long-handled hooks. This harms the growth potential of a tree by removing shoot apical meristem tissues and only provides difficult, thorny branches. When branches are exhausted, women fall back on noxious, dead stalks of spurges, family Euphorbiaceae. The last resort is animal dung. Only rarely will people cut down an adult tree for their own firewood needs. Men cut down trees for firewood for community events, large baptisms, weddings, or funerals, but even then, men prefer trees that have already died because these yield dry, more combustible wood.

Although women carry firewood for rural use, rural people load beasts of burden and carts to transport wood for sale in urban areas. So a town or city can produce land use changes far beyond its borders.

The low energy density of wood makes its transport onerous relative to the energy gained. Conversion of firewood to charcoal creates a product with double the energy per unit mass, but emits as waste heat up to two-thirds of the energy contained in the original wood. Charcoal makers cut down live and dead trees, particularly prizing sturdy tree trunks. In the field, they pile the wood, cover it with soil to form a kiln 1 to 3 m in
height and 1 to 3 m in diameter, and ignite a slow burn. Over 3 to 6 days, the wood converts to charcoal by partially anaerobic pyrolysis. Firewood harvesting can superimpose locally severe changes in biological diversity over wider alterations caused by long-term climate change. Global warming, the El Niño Southern Oscillation, and desertification all lead to systemic ecological changes at a regional scale. Embedded within these regions, firewood harvesting can reduce vegetative cover in less extensive areas where people depend on wood for their energy use.

The impacts of desertification in the West African Sahel clearly illustrate this complex situation. In Senegal, anthropogenic and climate factors caused a decline in forest species richness of one-third in the last half of the twentieth century (Gonzalez 1997). Rainfall in the Sahel has shown a persistent downward trend in the past four decades, with the rainfall average of all years since 1919 falling at Louga, Senegal (15°37’ N, 16°14’ W) from 470 mm in 1953 to 400 mm in 1993. Serious droughts have hit in the periods 1910–1914, 1942–1949, and 1968–1973. An increase in human population has coincided with the decline in rainfall. The population of Senegal doubled in the period 1945–1988, growing at a rate of 0.025 y⁻¹.

In Northwest Senegal, the average forest species richness of areas of 400 ha fell from 64 ± 2 species ca. 1945 to 43 ± 2 species in 1993. Moreover, densities of trees of height ≥ 3 m declined from 10 ± 0.3 trees ha⁻¹ in 1954 to 7.8 ± 0.3 trees ha⁻¹ in 1989. Both the fall in species richness of 33 ± 5% and the decrease in tree densities of 23 ± 5% translate to a rate of −0.8% per year.

In West Africa, rainfall increases and evapotranspiration decreases toward the equator, creating a gradient that differentiates species into three broad bands of increasingly mesic vegetation: the vegetation zones of the Sahel, the Sudan, and Guinea. In Senegal, arid Sahel species (e.g., Family Mimosaceae) expanded in the north, tracking a concomitant retraction of mesic Sudan (e.g., Family Caesalpiniaceae) and Guinean species (e.g., Family Bombacaceae) to the south. Vegetation zones shifted southwest 25 to 30 km in the period ca. 1945–1993 (Fig. 4), a rate of 500 to 600 m y⁻¹, foreshadowing the magnitude of projected shifts driven by CO₂-induced climate change. The historical change acted through a higher mortality among mesic species, leaving drought-resistant species to dominate the remaining tree cover. The most notable species that have experienced local extinctions include Dalbergia melanoxylon (Senegal ebony), Prosopis africana (ironwood), Sterculia setigera (mbep), and Tamarindus indica (tamarind).

Out of 215 ecological and socioeconomic variables, multivariate statistical analyses identifies rainfall and temperature as the most significant factors explaining the distribution and densities of trees and shrubs in Northwest Senegal. Rainfall and temperature override local anthropogenic factors.

Examination of dead trees along the coast supports a predominance of climatic over local anthropogenic factors. The sparsely populated coast offers a view of the state of the countryside before cultivation. Natural stands of Euphorbia balsamifera still occur there. In contrast, elsewhere in the Senegal Sahel, farmers have cut all natural stands of this species and replanted it...
along field boundaries. In the collective memory of local people, vast areas along the coast have not been cultivated. Dead trees still stand along the coast, but they show no ax marks or any sign that humans directly caused their death.

On a subcontinental scale, however, human activities may have caused the decline in rainfall. Deforestation of tropical rain forests in the Congo vegetation zone from the Republic of Guinea to Côte d’Ivoire may have reduced the evapotranspiration inputs essential to the maintenance of the Southwest Monsoon. Reduced rainfall over an extended period would reduce the vegetation cover in the Guinea zone. Thus in turn would decrease rainfall and vegetation in the Sudan, eventually reducing rainfall and vegetation in the Sahel. Thus, human activities in the distant rain forests may initiate a concatenation of climatic links that ultimately touch the Sahel.

Nevertheless, population growth has undoubtedly placed increasingly inordinate pressures on the area’s vegetative cover. In Northwest Senegal, rural firewood use exceeds firewood production from shrubs over 90% of the land area, affecting 95% of the rural population. The rural population density of 45 people km⁻² exceeded the 1993 carrying capacity of firewood from shrubs of 15 people km⁻² (range 1–21 people km⁻²). The rural population density has exceeded carrying capacity since 1996.

The standing biomass of trees across the research area decreased from 14 t ha⁻¹ in 1956 to 12 t ha⁻¹ in 1993, matching a cumulative firewood deficit in the same period of 2 t ha⁻¹. The reduction in standing biomass released carbon into the atmosphere at a rate of 60 kg C cap⁻¹ y⁻¹, somewhat less than the 100 kg C cap⁻¹ y⁻¹ released from the burning of fossil fuels, mainly by the urban industrial and transport sectors.

Not only do the quantitative uses of firewood and charcoal exceed the area’s wood production, but the fall in species richness has also reduced people’s options qualitatively. For example, rural women depend on two particular shrub species for firewood because of the size of the branches, high wood density, and ease of collection. Beyond that, few fallback species remain. The fraction of women that reported shrub species as most prevalent in firewood use fell from 87% ca. 1945 to 50% in 1993. With respect to traditional medicine, 25 useful species have diminished significantly. Furthermore, eight species that provided fruit, leaves, and gum in past droughts have disappeared from as much as 53% of their range. If a grave famine hit the area in its current condition, people would not be able to find the emergency foods that saved others in past episodes.

In the Sahel, the natural regeneration of local species could halt the declines in biodiversity and forest biomass. Natural regeneration is a traditional practice in which farmers and herders protect and promote the growth of young native trees. Traditionally, local people protect small trees that have germinated naturally or regrown from roots, prune them to promote growth of the apical meristem, and, if necessary, set a stake to straighten the small tree.

Natural regeneration has expanded Acacia albida from an original restricted range along rivers in Southern Africa over thousands of km² up through the Sahel and the Sudan. In Senegal, the Sereer have protected dense parks of Acacia albida and Adansonia digitata in wide areas south of the research area. On the Mossi Plateau in Burkina Faso, farmers have similarly protected expanses of Butyrospermum parkii for the valuable oil from the tree’s seeds. Across the Sahel, leather workers protect Acacia nilotica adansoni for the tannin enriched bark.

Natural regeneration requires no external inputs. It concerns species well known and appreciated by villagers. It focuses on young trees that have demonstrated their hardiness by surviving with no human caretaker, no watering, and no special treatment. Furthermore, natural regeneration not only augments the supply of wood, poles, fruit, medicine, and other products, it puts trees where farmers and herders really need them: in fields to maintain soil fertility and in pastures to provide forage.

Although photosynthetic activity in semiarid lands is an inefficient conversion of the total available solar radiation, the inefficiency of human tools renders end uses even more inefficient in the final conversion into heat and light. Table III shows this energy chain from sunshine to wood end use in the West African Sahel.

Gonzalez 1997.
Therefore, another practice that can serve to conserve vegetative cover in rural areas dependent on firewood is the use of improved efficiency cook stoves. In many areas, women customarily cook with a kettle over an open fire. International development agencies have worked to develop and introduce stoves such as the ban ak suuf in Senegal, a horseshoe-shaped hearth constructed from clay and cow dung that provides a more enclosed combustion space to more effectively channel heat to the cooking vessel. The lorena in Guatemala is another earthen stove. The jiko in Kenya and sakkanal in Senegal are enclosed metal or ceramic charcoal stoves that more effectively contain heat than do traditional open charcoal burners.

V. FUTURE ENERGY PATHS

Human energy use directly alters patterns of biodiversity through changes in land use and through industrial pollution. Indirectly, human energy use is changing global biodiversity through the emission of greenhouse gases that cause global climate change and through other broad environmental effects of industrialization. Not only does the direct processing of energy generate environmental impacts, but the end uses that convenient energy forms make possible produce impacts locally and globally. Table IV summarizes the major environmental impacts of human energy use on biodiversity. Almost every source requires land (Table V), a requirement that leads to habitat fragmentation and destruction. Globally, the climate change caused by CO2 emissions constitutes the major impact of fossil fuels, but nonfossil fuel sources also produce air and water pollution. No energy transformation system operates without negative environmental effects, yet renewable sources generally restrict harmful effects to the capital formation stage and do not produce much ongoing pollution.

Holdren and Ehrlich (1974) proposed that environmental impact is equivalent to the multiplicative effect...
of population, affluence, and technology.

Environmental Impact = Population \times \frac{Resource use}{Person} \times \frac{Environmental Impact}{Resource use}

People now call this identity the IPAT equation (impact = population \times affluence \times technology). Because the environmental impact of human energy use is proportional to the rate of energy use, and energy use is proportional to economic production, then the IPAT equation for energy becomes

Environmental impact \propto \frac{energy use}{GNP \times Person} \times \frac{GNP}{energy use}

Here, economic production per person indicates the level of material affluence, while energy use per unit of economic production indicates the level of technological efficiency. This highlights the great leverage that both energy conservation and efficiency wield to reduce the environmental impact of energy use. Indeed, improvements in energy efficiency reduced the energy intensity of economic activity in the United States by nearly one-third between 1973 and 1993.

For a 2300 AD global population of 10 million people to stay within the environmental limits of the earth, Holdren (1991) suggests that industrial countries im-

prove their energy efficiency to allow for an increase in economic activity in the nonindustrial countries so that everyone converges on an average use of 3 kW per person. This would increase total world energy use to 30 TW, more than double today’s total. Imagine a world with twice as many nuclear power plants, coal mines, automobiles, and other energy infrastructure as today. Because many environmental impacts increase exponentially, the total impact will be much more than double.

Yet, the historical path of industrialization has left the world with only costly and environmentally disruptive energy alternatives. The earliest exploitation of fossil fuels depleted the most convenient oil and gas deposits. This is why fossil fuel production over time follows the bell-shaped Hubbert Curve. Not only has this left the current generation with deposits that are farther in polar and desert regions, deeper underground, and dispersed, but the low-cost energy has also shaped the expectations of people around the world for inexpensive on-demand energy services. Societies even subsidize the provision of convenient energy through infrastructure support to energy industries, tax breaks to oil drillers, preferential treatment to automobile companies, and other schemes.

The depletion of nonrenewable resources (Table VI) and other serious environmental and social constraints hobble most energy options for the future: recoverable oil and gas reserves will last only another 30 years; coal burning releases the principal agent of global warming, CO₂; biomass energy requires vast amounts of land; the small number of exploitable sites limits the potential

for hydroelectric and wind power; and health and safety concerns prevent expansion of nuclear energy.

As a response to these constraints, governments, industry, and academia have placed enormous effort into the development of technologies such as electric vehicles, hydrogen cars, fuel cells, and nuclear fusion. Still, the future of human energy use may not lie with exotic devices. Instead, renewable energy sources, conservation, and efficiency of end use could form the future energy path of the world. Amory Lovins (1977) called this the “soft path.” This would occur if societies set as their goal the provision of services, not just the acquisition of energy stocks and devices. In effect, people don’t require light bulbs, they need illumination.

   Arguments
II. Duties to Protect Biodiversity: Obligations
   Human and Divine
III. Biodiversity and Human Flourishing
IV. Environmental Philosophies

GLOSSARY

anthropocentrism Position that only human beings
   have moral worth or intrinsic value.
biocentrism Position that all living beings have moral
   worth or intrinsic value.
deep ecology Activist philosophy that advocates radical
   personal and political change to protect wild
   nature.
ecofeminism Liberation philosophy that draws con-
   nections between preserving nature and promoting
   women’s rights.
environmental ethics Philosophical discipline that
   specifies proper human relationships to the natural
   world.
ethical holism Position that complex aggregates such
   as species, ecosystems, or human societies have intrin-
   sic value.
instrumental value Value of something relative to hu-
   man interests or desires.
intrinsic value Value of something independent of its
   value to people.

ETICS IS THE BRANCH OF PHILOSOPHY that seeks
knowledge of human flourishing and right conduct to-
ward others, so that we may act upon it. Modern philo-
osophers have tended to limit their ethical concern to
human beings, but throughout history people have also
attempted to cultivate proper relationships to the rest
of nature. Recently philosophers have turned to this
topic, largely in response to environmental degradation
and the loss of biodiversity, and have created a new
discipline: environmental ethics. Environmental ethi-
icists attempt to specify appropriate human relation-
ships to the nonhuman, natural world. In the course
of their work they have developed strong ethical argu-
ments for preserving biodiversity. They have also chal-
enged conventional views of happiness and human
welfare and the materialistic values at the base of much
modern life. While environmental ethics treats the full
range of environmental issues, from air pollution to
nuclear risk assessment, this article focuses on ethical
issues directly related to the preservation of biodi-
versity.
I. DUTIES TO PROTECT BIODIVERSITY: INTRINSIC VALUE ARGUMENTS

A. From Economics to Ethics

Biodiversity has great economic value, both direct and indirect. Direct economic values are provided by wild game, seafood, fuelwood and timber products, and indigenous and high-technology medicines. Indirect economic values accrue from biodiversity's roles in waste disposal, climate regulation, protecting soil and water resources, recreation and ecotourism, and much more. Both directly and indirectly biodiversity safeguards or adds to human wealth, often justifying its protection in purely economic terms.

Thus economic arguments by themselves provide a basis for valuing and protecting species, especially when we expand our concept of economic value from short-term, next-quarter profits to include longer-term and indirect benefits. But economic arguments can also provide grounds for extinguishing species or for saving one species rather than another. In conventional economic terms, low value will be given to species having small populations or limited geographical range, small physical size or unattractive appearance, no immediate use to people, or no relationship to other species of economic importance. Such qualities may characterize a substantial proportion of the world's species, particularly insects and other invertebrates, fungi, nonflowering plants, bacteria, and protists. Halting profitable developments or making costly attempts to preserve these species may not have any obvious economic justification. In some circumstances, economic justification could exist for destroying an endangered species, particularly organisms that cause disease or attack crop plants. Still, many people believe that such destruction is morally wrong even if it is economically profitable.

To say that an object has economic value is to say that it is useful to human beings or that they desire to possess it. Put another way, it has an instrumental value: someone can use it as an instrument for his or her purposes. On the other hand, we recognize that at least some entities, such as human beings, have value regardless of whether anyone else values or uses them. These entities have an intrinsic value: a value that is grounded not in their usefulness to others, but in what they are themselves.

Human beings, we usually think, have both instrumental and intrinsic value. Because we have intrinsic value we possess certain rights that no one can legitimately infringe, even if it is in their self-interest to do so. Conversely we have certain duties towards other people that specify how we should or should not treat them in various situations. We cannot help but look at the people we interact with each day in terms of their usefulness to us, but if we look at them solely in these terms we disrespect their (and our) humanity and if we treat them solely as a means to our own ends we are likely to behave immorally.

Many conservationists argue that similar duties restrict the morally acceptable treatment of wild nature. They consider it wrong to destroy a rare woodland or cause a species to go extinct, even if this action is in an individual's or corporation's self-interest. Not only have we no right to destroy any species, we have a moral responsibility to actively protect species from extinction as the result of our activities. Opponents counter that this position is illegitimate because only human beings have intrinsic value. Unless our actions affect other people, directly or indirectly, any treatment of the natural world is morally acceptable.

B. Extensionist Arguments for Intrinsic Value

Proponents provide both extensionist and nonextensionist arguments for the intrinsic value of wild nature. Extensionist arguments ask what qualities give intrinsic value to human beings, then assert that some other beings possess these same qualities. Therefore, they conclude, we should recognize the intrinsic value of these other beings and extend proper treatment to them.

One common justification for valuing human beings is our ability to reason. But some of the so-called "higher animals" also seem to possess the rudiments of reason. Chimps and gorillas have been taught sign language involving several hundred words; wolves have an elaborate social life and the ability to coordinate long hunts; dolphins, whales, and other cetaceans send complex signals that we are just beginning to understand. Many argue that because of these factors, we should not hunt these animals for food or sport, use them in research, or in general treat them solely as means to our own ends.

Other philosophers believe that sentience—the ability to perceive the surrounding world and feel pleasure and pain—demands moral consideration. The extensionist argument here states that because pain is bad we should avoid inflicting pain unnecessarily on others who can feel it—even if those others have fur, feathers, scales, or numerous legs. Immoral actions against human beings are wrong, at base, because they cause unnecessary pain; actions that cause other animals unnec-
essential pain are likewise immoral. Millions of people around the world act on such beliefs by abstaining from eating animals or using products that can only be procured by killing or harming them. Even most meat-eaters accept that inflicting gratuitous pain on animals is wrong, suggesting a widespread belief that where there is sentience there exists some moral responsibility.

One possible problem with the extensionist arguments just discussed, from the point of view of conservationists, is that they only encompass certain organisms. Basing intrinsic value on some rudimentary form of reasoning or complex mental experience would appear to rule out most animals, for example, almost all invertebrate species. Basing moral consideration on the ability to feel pain includes a wider class of animals, but again many simpler animals and all plants, fungi, and single-celled organisms are ruled out.

However, extensionist arguments can be extended further by recognizing that all organisms have a drive to stay alive and reproduce. In the same way that we acknowledge the rights of people to live, have children, and satisfy basic needs, we may extend these rights to individuals of all species. In his autobiography, Albert Schweitzer maintained that “a man is ethical only when life, as such, is sacred to him, that of plants and animals as that of his fellow men, and when he devotes himself helpfully to all life that is in need of help.”

This position may lead to a very demanding code of conduct! Believers in strict biocentric equality assert that it is always wrong to kill individuals of any species (because of their intrinsic value) unless we need to do so to survive. Others believe that using nature to provide necessities and some measure of comfort is morally acceptable, but not to provide luxury goods. In this view, cutting down trees for firewood or to build a modest house is morally acceptable, particularly if this is done sustainably, whereas harvesting mahogany trees from rain forests to make expensive furniture for wealthy individuals half a world away is morally unacceptable. Whatever the particular judgments made, recognition of an intrinsically valuable organic world leads to distinctions between essential and inessential human uses and to a more limited use of natural resources.

C. Nonextensionist Arguments for Intrinsic Value

In addition to extensionist arguments, which point up similarities between wild nature and intrinsically valuable humans, there are arguments that find value in nature without referring to such similarities. Some believe it is a mistake to value other beings only for the ways in which they resemble humans. Writing in The Monist in 1992, Robert Elliot suggested that natural organisms may have the following properties that give them intrinsic value: “diversity, stability, complexity, beauty, harmony, creativity, organization, intricacy, elegance, and richness.” These are qualities of natural organisms that we can appreciate—and that may call forth responses of personal restraint and active protection.

All species represent unique biological solutions to the problem of survival. They have solved the challenges placed before them by their environments and thrived. Some people see a value in this creativity and time-tested uniqueness. Others appreciate the beauty and elegance of the natural forms created by this process. Still others value the complexity and ingenious structures that science and close observation have revealed. People who know and value this uniqueness, beauty, and complexity feel a special horror at its permanent disappearance. After all, if an individual dies it may be replaced by another individual more or less the same, but take away the last passenger pigeon or giant moa and their like will never return. Nonextensionist arguments thus support preservation of species as well as protection of individual organisms (see Section 1.E).

Species interact in complex ways in natural communities. The loss of one species may have far-reaching consequences for other members of the community: other species may become extinct or the entire community may become destabilized. As we learn more about global processes we are finding out that many chemical and physical characteristics of the atmosphere, the climate, and the ocean are linked to biological processes in a self-regulating manner. More diverse biological communities may be better able to deal with environmental disturbances such as drought and global climate change. For these reasons, if we value some species, we should arguably protect all species.

D. Anthropocentric Denials of Intrinsic Value

Skeptics reply that even though some people do value non-human organisms and species, we are not obligated to do so, because only human beings have intrinsic value or genuine rights. Humans have a value beyond all other beings because only we are fully conscious and rational. Unless our actions affect other people, directly or indirectly, any treatment of the natural world is morally acceptable.

Such a viewpoint is anthropocentric—locating value solely in humans—and to many it seems the most obvious common sense, while departures from it seem irr
tional or overly sentimental. The appellation "tree hugger" expresses this view, suggesting inappropriate sentiments toward trees, leading to inappropriate actions. It also suggests a callous disregard for the interests of people who cut trees for a living, whom we really should care about (consider the bumper sticker "Hug a Logger, Not a Tree"). People who value nature counter that anthropocentrism is selfish and that speciesism—the privileged treatment of one species over another—is no more justified than racism or sexism.

Although the debate between anthropocentrists and biocentrists has tended to incorporate all the uncertainties attending ethical justification in general, some clarification may still result. Charges of irrationalism to the contrary, it is possible to love and value nonhuman nature and act on this view. The challenge to biocentrists is to fashion fulfilling lives that limit their negative environmental impacts and help preserve and celebrate nature. Anthropocentrism also remains a rationally defensible position, which may be consistently acted upon. Anyone who values humanity based on qualities that we share with other species, however, cannot consistently deny intrinsic value to those other species. Furthermore, anthropocentrists who value humanity primarily for our ability to reason may consider the many arguments in favor of lessening pollution and preserving wild nature that appeal to our rational self-interest. Anthropocentrists are more likely than biocentrists to accept some amount of pollution in rivers or the extinction of certain species, but they also acknowledge human needs for clean air and drinking water, the enjoyment we get from fishing, swimming, and canoeing, and the value of biodiversity to science, art, and business. When it comes to particular environmental policies, anthropocentrists and biocentrists may find considerable common ground.

E. Ethical Holism

The preservation of biodiversity seems to demand that the needs of endangered species take precedence over the needs of individual organisms. For example, the U.S. National Park Service killed hundreds of introduced rabbits on Santa Barbara Island off the California coast to protect a few plants of the endangered Santa Barbara live-forever (Dudleya traskiae) (Fig. 1). In this case, one endangered species was judged to be more valuable than hundreds of individual animals of a common species. Similarly, conservation biologists would not find it acceptable to destroy the last remnant of a rare biological community even if every species living there could be maintained in captivity; the ecological interactions and evolutionary processes of the community would be lost if the species only lived in captivity. These examples illustrate that most conservationists are holists, finding value in larger groupings, such as species and biological communities. They are thus sometimes willing to sacrifice the interests of individuals to preserve species and communities.

Many writers, especially animal welfare advocates, have difficulty assigning rights to species. Peter Singer and Tom Regan, two prominent philosophical animal welfare advocates, argue that species are not conscious entities and so do not have interests. In their view, to sacrifice the genuine interests of an individual animal, who can suffer or possess rights, to the imagined interests of a species, which cannot, is mistaken. Many animal welfare advocates also reject conservationists' spe-
cial concern for native species over exotics: an animal is an animal, with a greater or lesser ability to suffer, and this ability should determine our actions, rather than its point of origin.

On both biological and ethical grounds, however, most conservation biologists argue that species, rather than individual organisms, are the appropriate targets of conservation efforts. All individuals eventually die; it is the species that continues, evolves, and sometimes forms new species. In a sense, individuals are temporary 
representatives of species. Whether or not we allow them rights, species carry great value as the repositories of the accumulated experience and history of millions of previous life-forms through their continuous, evolutionary adaptation to changing environments. The premature extinction of a species due to human activities destroys this natural process and renders its history. It can be regarded as a "superkilling," because it kills future generations of the species and eliminates whole lines from the processes of evolution and speciation.

Furthermore, conservationists typically argue that species should be prevented from spreading beyond their natural ranges as a result of direct or indirect human activity. For example, the zebra mussel (Dreisena polymorpha) is native to the Caspian Sea, but it has recently become an aggressive invader of North American aquatic habitats (Fig. 2). Arguably this species should be destroyed whenever possible in North America, for two reasons. First, exotics often displace native species, sometimes contributing to their extinction. To prevent this loss of biological diversity we destroy individual exotics, on the assumption that the exotic species will continue to thrive in its native habitats. Second, and more controversially, many conservationists deny intrinsic value to individual plants and animals that have spread beyond their natural range due to human activities. Part of what gives a species value is its unique evolutionary history and its ecological roles in native habitats, both of which are tied to particular places and biological communities. When these species instead invade new natural areas and destabilize or radically change their species composition, these justifications of their value no longer hold. Exotic species contribute to biodiversity in their native habitats but often diminish biodiversity when they become established and common in new locales.

II. DUTIES TO PROTECT BIODIVERSITY: OBLIGATIONS HUMAN AND DIVINE

A. Duties to Humans

That human beings have direct moral duties to other species remains controversial; that we have direct moral duties to other human beings is not (although great disagreement remains regarding their scope). Our duties to other human beings may support protection of the environment and preservation of biodiversity, based on their instrumental value to intrinsically valuable people.

We have responsibilities to our neighbors and fellow citizens. Because of this we must arguably minimize damage to the natural environment, since such damage harms not only other species but people as well. Increasingly, connections are being made between environmental pollution and high levels of human disease. For example, massive environmental pollution in the former Soviet Union has greatly increased cancer, birth defects, lead poisoning, and lung disease among the population. Much pollution and environmental degradation is unnecessary and could be minimized with better planning. Often pollution occurs because corporate leaders are unwilling to spend money to prevent it, despite the resulting ill effects on the health, wealth, or happiness of other people. Citizens must recognize the biological and social costs of environmental damage and force corporations to be good neighbors and governments to enact and enforce strong environmental laws, for the common good.
We also have responsibilities to future generations. Economic decision making tends to focus on the short term and it is this economic system that is driving environmental change and degradation. In response, many ethicists have emphasized the importance of intergenerational justice. Humanity's unprecedented numbers and technological power mean that one generation can now radically remake the earth that the next will inherit, for better or worse. If in our daily living we degrade the natural resources of the earth and cause species to become extinct, future generations will pay the price in terms of a lower quality of life.

This truth gives us arguments not just for keeping ecosystems safe for present human health, but also for preserving biodiversity for future human use, enjoyment, and development. For example, if species and wild places are lost, children will be deprived of one of their most exciting experiences in growing up—the wonder of seeing "new" animals and plants in the wild. These concerns are a powerful motivating force for the members of organizations such as the Sierra Club and The Nature Conservancy, who see themselves as land stewards preserving biodiversity for future generations.

Writing in the *Encyclopedia of Environmental Biology* in 1995, Holmes Rolston predicted: "It is safe to say that in the decades ahead, the quality of life will decline in proportion to the loss of biotic diversity, though it is often thought that one must sacrifice biotic diversity to improve human life." Of course, this contention is debatable. Many argue that job creation and increased wealth are more important to future generations than the preservation of biodiversity. Debate on this issue, while inconclusive, is essential, because it forces us to specify the actual, long-term benefits of development projects and the sorts of societies we want to create for our children. Given our unprecedented power and the tendency to put personal interests above the common good, even inconclusive debate may be a force for creating a better future for all.

At a minimum, our duties to posterity seem to require us to live sustainably—that is, limiting our consumption so as not to degrade essential life-support systems or deplete natural resources that future generations will need. The world's governments have formally recognized this through treaties governing air pollution, whale hunting, and disposal of wastes in the ocean. One important treaty, the Montreal Protocol of 1987, reduced the permitted use of ozone-depleting chlorofluorocarbons, leading to a phase-out of production three years later. The grave dangers these chemicals posed to future generations, with their potential to thin the earth's protective ozone layer and cause millions of new cases of deadly skin cancer, clearly outweighed the interests of producers and users of CFCs, especially since many of those uses were not essential to human survival (e.g., in luxury items such as hairsprays and air conditioners) and alternatives were available or quickly developed for most uses.

Similar appeals to the good of future generations have so far proved less successful in convincing world governments to reduce fossil fuel use to slow global climate change. This is partly due to strenuous lobbying by oil and automotive corporations and oil-producing nations, whose leaders have implicitly placed short-term profits above the health and well-being of future generations. Partly though it is because the risks of increased fossil fuel use, though grave, are less certain than those associated with continued use of CFCs, while the economic costs of decreasing fossil fuel use are far greater.

Human maturity leads naturally to self-restraint and a respect for others. Many conservationists agree with Arne Naess (1989), who writes that the further maturation of the human species will involve an "identification with all life forms" and "the acknowledgment of the intrinsic value of these forms" in an expanding circle of moral obligations. Moving outward from oneself, the circle would include duties to our family and relatives, our local community, our country, all humanity, mammals (Save the Whales!), all animals (Save the Snail Darter!), all species (Save the Yellow Lady Slipper Orchid!), ecosystems (Save the Rain Forest!), and ultimately the whole earth (Fig. 3). Such an expansion of ethical concern involves new limitations on acceptable actions, but also new opportunities for personal growth and flourishing.

Although some worry that recognizing intrinsic value in nature devalues human beings, many environmental philosophers argue that respect for human life and human diversity is compatible with a respect for nonhuman nature. Citizens of all countries will be more likely to accept their responsibility for protecting biological diversity, they assert, when they have full political rights, a secure livelihood, and an awareness of environmental issues. Some of the most exciting developments in conservation biology involve supporting the economic development of disadvantaged rural people in ways that are linked to the protection of biological diversity. Helping poor women establish sustainable plots of cash crops and achieve a degree of economic independence may reduce the need to overhunt wild species. Working with indigenous people to establish legal title to their land may give them the means to protect the biological communities in which they live.
Actions taken to protect species and biological communities should whenever possible benefit people as well.

B. Duties to God: Religious Stewardship

Various preindustrial cultures successfully coexisted with a rich local flora and fauna for hundreds of years, in part because their religions and societal ethics encouraged personal responsibility and thoughtful use of resources. People in these societies respected wild animals and plants even as they harvested them or borrowed their habitat for human purposes. For example, the Cherokee Indians of the southeastern United States spoke special prayers to the deer that they killed, telling the deer spirit that they indeed needed the meat, that they would not waste it, and that they would bury the bones with due solemnity. Traditional peoples often treated rivers, mountains, and other ecosystems as sacred places to be approached with reverence and an appreciation for what they were, rather than for what human beings could make of them.

Many modern religious adherents abhor the destruction of species, because they are God's creation. If God created the world, then presumably the species God created have value. Within the Jewish and Christian traditions, human responsibility for protecting animal species is explicitly described in the Bible as part of a covenant with God. The Book of Genesis describes the creation of the earth's biological diversity as a divine act, after which "God saw that it was good" and "blessed them." In the story of Noah's Ark, God commanded Noah to save two of all species—not just the ones human beings found useful. God provided detailed instructions for building the ark, an early species rescue project, saying "Keep them alive with you." After the flood subsided, the animals were released to repopulate the earth. This story, versions of which were told throughout the ancient Near East, can be interpreted as an early awareness of the importance of biological diversity.

The prophet Mohammed, founder of Islam, continued this theme of human responsibility, saying "The world is green and beautiful and God has appointed you as His stewards over it. He sees how you acquit yourselves." Many other religious traditions also support the preservation of nature. For example, Hinduism locates divinity in certain animals and recognizes a basic kinship between humans and other beings, including the transmigration of souls from one species to another. A primary ethical concept in Hinduism and other Indian religions, such as Jainism and Buddhism, is ahimsa—avoiding unnecessary harm to life. In attempting to live this ideal, many religious people become vegetarians and live as simply as possible.

III. BIODIVERSITY AND HUMAN FLOURISHING

Economic arguments stress that we should preserve biological diversity because it is in our material self-interest. Ethical arguments based on the intrinsic value of wild nature, our duties to other human beings, or our duties to God stress that we should sometimes act altruistically; that is, we should set aside our personal interests to preserve biological diversity. A second kind of ethical argument appeals to a fuller understanding of our self-interest, arguing that preserving biodiversity and developing our knowledge of it will make us better and happier people. The following are the main arguments for preserving biodiversity in our own enlightened self-interest.

A. Health and Wealth

It cannot be repeated too often that biological diversity preserves our basic life-support systems of food production, water supply, oxygen replenishment, waste disposal, soil conservation, and more. People are healthier and more productive in clean, intact environments. We
depend on this and should value it. Similarly, biodiversity allows us to create tremendous economic wealth, directly and indirectly. An article published in Nature in 1997 by Robert Costanza and others, “The Value of the World’s Ecosystem Services and Natural Capital,” estimated that the world’s ecosystems produce $32 trillion per year of value to people, substantially higher than the $18 trillion per year of goods and services those people produce themselves. In other words, human society could not exist without what the natural world provides us for free, nor could we afford to pay for substitutes even if they existed.

B. Aesthetic and Recreational Enjoyment

Nearly everyone enjoys wildlife and landscapes at an aesthetic level and this is part of a good life. The beauty of a field of wildflowers in Glacier National Park or a migrating warbler on a spring morning in a city park enriches the lives of those who appreciate them. For many people, high quality of life involves experiencing nature first-hand. Simply reading about species or seeing them in museums, gardens, zoos, or videos will not suffice. Hiking, canoeing, nature photography, and bird watching are physically, intellectually, and emotionally satisfying.

Hundreds of millions of people spend tens of billions of dollars annually in these pursuits, proof enough of their value. As the world becomes more crowded, it becomes ever clearer that these activities are in competition with other human uses. We are creating a world with ever-diminishing opportunities for aesthetic and recreational encounters with wild nature (Fig. 4). If species and ecosystems are not to disappear altogether, they must be consciously preserved.

C. Artistic Expression and Scientific Knowledge

Throughout history, poets, writers, painters, sculptors, and musicians of all cultures have drawn inspiration from wild nature. Nature provides countless forms and symbols for visual artists to render and interpret, while poets have often found their greatest inspiration in either wild nature or pastoral countrysides (Fig. 5). Preserving biological diversity preserves possibilities for all artists. It also allows those of us who appreciate such creative acts access to the sources and experiences that inspired them. A loss in biological diversity could very well limit the creative energies of people in the future and thus restrict the development of human culture. For example, if many species of whales, butterflies, and

![Figure 4](https://example.com/fig4.png)

**Figure 4** Reaching out. Most people find interacting with other species to be an educational and uplifting experience. Here people greet a minke whale that is being rescued after it became entangled in a trawler’s gill net; the fish behind the whale was attached to the net to keep the whale at the surface so it could breathe. Later, rescuers were able to release the whale from the netting. (Photograph by Scott Kimis, New England Aquarium.)
If *Homo sapiens*’ closest living relatives, the great apes, disappear from the wild, we will lose important information regarding human physical and social evolution.

**D. Historical Understanding and Religious Inspiration**

Knowing nature, both scientifically and through personal experience, is a key to self-knowledge and an understanding of human history. In walking the landscapes that our ancestors walked, we gain insight into how they experienced the world, at a slower pace and without mechanized aids. People often forget just how recently humankind has moved to ultrafast transportation, fully illuminated cities that shut out the night, and other aspects of modern life. Preserving natural areas allows us to develop our historical imaginations.

Many religions have traditions of “wandering in the wilderness” in order to commune with God or with spirits. In the Western tradition, Moses, Isaiah, Jesus, and St. Francis of Assisi all sought out the solitude of wilderness. So did the Chinese sage Lao-tzu, the Japanese Zen poet Basho, and generations of Lakota vision-seekers. Being in nature allows us to clear and focus our minds and sometimes experience the transcendent. When we are surrounded by the artifacts of civilization, our minds stay fully focused on human purposes and our everyday lives. Religion probably would not disappear from a totally tamed human environment, but perhaps it would become diminished for many.

In brief, while the preservation of biodiversity sets limits to some human activities, it is a prerequisite for our continued enjoyment of others. There are good reasons to believe that preserving and exploring biodiversity can make us better, happier people. Many conservationists are convinced that a better understanding of our true self-interest would lead to greater efforts to protect biological diversity.

**IV. ENVIRONMENTAL PHILOSOPHIES**

**A. Deep Ecology**

Paul Sears, recognizing that increased knowledge would lead to the questioning of destructive practices common in modern society, and often taken for granted, called ecology a “subversive science.” During the twentieth century, ecologists, nature writers, and practicing environmentalists have increasingly articulated an appreciation of nature and spoken of the need for changes in human lifestyles to protect it. “Green” political parties and activist conservation organizations such as
Greenpeace, EarthFirst!, and India’s Chipko movement have appeared throughout the world.

One well-developed environmental philosophy that supports this activism is known as deep ecology. Deep ecology builds on two basic premises: biocentric equality and self-realization. Biocentric equality expresses the intuition... that all things in the biosphere have an equal right to live and blossom and to reach their own individual forms of unfolding” (Devall and Sessions, 1985). Humans have a right to live and thrive, but so do the other organisms with whom we share the planet.

Self-realization describes a striving to grow, develop, and find fulfillment. Human beings are assumed to share this goal with the rest of nature. In the case of humans, deep ecologists believe that true self-realization involves spiritual growth and an expansion of knowledge and concern, rather than an increase in material wealth. Individual human self-realization should lead to a concern with all of nature: the preservation and development of the larger wholes to which we belong, including both human and natural communities. Deep ecologists articulate this position in opposition to a “dominant worldview” that makes human concerns paramount and views human happiness in materialistic terms (see the following table). Deep ecology’s idealism and its call to action make it an appealing philosophy for people concerned with protecting biodiversity.

B. Ecofeminism

Ecofeminism represents another recent, important development within environmental ethics. Ecofeminists see a connection between the domination of women and the domination of nature. They attempt to specify links between these two forms of domination, and advocate both environmental protection and full, equal rights for women.

Like deep ecologists, ecofeminists argue that how we conceptualize wild and human nature has important ethical consequences. Karen Warren argues that some conceptual frameworks are inherently oppressive, because they split the world up into “value dualisms, i.e., disjunctive pairs in which the disjuncts are seen as oppositional (rather than as complementary) and exclusive (rather than as inclusive), and which place higher value on one disjunct rather than the other” (Armstrong and Bozler, 1998). Thus men are privileged over women, human culture over nature, animals over plants, and reason over emotion. The inferior disjuncts tend to be lumped together: women may be seen as closer to nature, more emotional, or less rational. Such conceptual frameworks legitimize discriminatory treatment of those “others” who fall on the wrong side of these value dualisms.

Ecofeminists launch a three-pronged attack on such a “logic of domination.” First, they may deny that certain differences exist, that they are hard and fast differences, or that they are as extreme as they are portrayed. For example, most ecofeminists simply deny that women are less rational or more emotional than men. In like fashion, they may point up similarities between humans and the other animals and downplay our differences. Second, ecofeminists may deny that actual differences make some beings morally superior to others. Human beings are superior reasoners compared to frogs, but that does not mean that we are therefore morally superior, in the sense that our interests should always trump theirs. Third, ecofeminists may deny that moral superiority underwrites domination. Even if humans are morally superior to frogs, it may still be wrong to kill them for food or destroy the last members of a rare frog species to create a new subdivision. Perhaps the proper response to those inferior to us in abilities or moral value is care and restraint.

C. Humanism: Our Default Mode

Like deep ecologists and ecofeminists, conventional ethical philosophers, including Kantians, utilitarians, and theologically grounded ethicists, have begun to

address environmental issues. Most philosophers who have considered these matters have found strong reasons to support environmental protection. As previously noted, biocentrists and anthropocentrists may agree on a wide range of measures to protect the environment, despite great philosophical differences.

Still, some philosophers and many members of the general public remain unconvinced of any moral imperative to protect biological diversity. Their position may be characterized as humanism, a philosophy committed to the following propositions:

1. Biological diversity exists for humans, has no value apart from humans, and need not exist apart from humans.
2. The transformation of wild nature into natural resources adds value to nature, since nature possesses value only in human use. Indeed, the ever more thorough transformation of wild nature allows increased human numbers to lead longer, happier, and better lives.
3. The creation of just societies filled with flourishing individuals is the highest achievement of which humans are capable. We should judge ourselves based on our technological, scientific, artistic, and social progress—not on whether we preserve nature.

Like the philosophies discussed earlier, humanism may be developed in a variety of ways. A humanist’s ideal society may be more or less egalitarian, wealthy, or stable, and more or less racially and culturally diverse. But humanists share a belief in the centrality of humans. They generally applaud increased human numbers, wealth, and technological power and the development of new arts and activities that flourish in highly artificial environments. For these reasons they see little to lament in the loss of biodiversity.

Humanism may be called humanity’s default mode, since current trends are moving us more and more in this direction, whether it is desirable or not. We are creating a world with much less biological diversity and this artificial world has come to seem normal, indeed natural, for many people. It is not, however, inevitable. Human beings can reconnect to nature and curb our activities that threaten it. Environmental ethics reminds us that we have many reasons to value and protect earth’s remaining biological diversity.

GLOSSARY

biological integrity Wholeness of a living system, including the capacity to sustain the full range of organisms and processes having evolved in a region.
biota Living things, in particular, the flora and fauna of a region.
biotic impoverishment Systematic reduction in the earth's capacity to support life.
environment Surroundings; the complex of physical, chemical, and biotic factors acting upon a living system and influencing its form and survival.
health A flourishing condition, well-being; capacity for self-renewal.
impact A forceful contact; a major effect of one thing on another.

ALL LIVING THINGS influence their environment. For the first time in the earth's history, however, the environmental impact of one species, Homo sapiens, is the principal agent of global change. Humans' most harmful impact is worldwide degradation of living systems—an impact that threatens humans' own life-support network. The 21st century's greatest challenge for scientists, decision makers, and citizens worldwide will be to understand and control human environmental impact and to protect the health and integrity of the biosphere.

I. NATURAL AND HUMAN DISTURBANCE

On the outermost rocks of scenic Big Sur's windswept headlands live rubbery palm tree look-alikes called sea palms (Postelsia palmaeformis). Graceful forests of these brown algae extend along the Pacific coast from central California northward to Alaska, always where the waves hit hardest. For organisms living from the high-tide line to the lower surf zone, wave action is life renewing, bringing in oxygen and nutrients and carrying away reproductive products to colonize other shores. Sea palms are able to colonize rocky open places that other intertidal organisms cannot; they thrive on the violence of the waves.

A few miles north of Big Sur, fields of artichokes,
brussels sprouts, and strawberries stretch to the seaward edge of the coastal plain. These boulderfields have been farmed for two centuries by successive waves of European settlers. The area's land vegetation is dominated by nonnative plants brought in with agriculture. Countless streams and rivulets carry seaward a legacy of eroded soil, fertilizers, and pesticides. Many small creeks are choked with algae, which flourish because of excess nitrogen and phosphorus from fertilizers and sewer outfalls; many plants and animals die or are otherwise harmed by the eroded soils and seeping chemicals. Even before farming and European settlement, however, humans were shaping the landscape: for thousands of years, native Costanoan people harvested shellfish from the intertidal zones and set fires to burn off woody shrubs and trees in favor of the grassland they preferred. Along this coast and others around the world, relentless wave action and human occupation are both driving forces of landscape change; both can be said to "disturb" the environments they influence. Both forces have an environmental impact, but the effects of the natural disturbance differ fundamentally from the effects of human-driven change. Over millennia, organisms evolve to contend with routine disturbances in their natural environments. Those that do not adapt go extinct. Those that survive are molded by evolution and biogeography to succeed in their environments, developing ways to coexist. 

II. HISTORY OF HUMAN IMPACTS

All organisms change their environment as they live, grow, and reproduce. Some organisms, like beavers or elephants, change their surroundings so dramatically that they have been called "ecosystem engineers." Beaver dams alter the flow of rivers, increase dissolved oxygen in downstream waters, create wetlands, and modify streamside zones. African elephants convert vast areas of wooded savannah to open grassland by toppling trees as they browse. Change brought about by living things, including the first humans, has been slow and incremental in evolutionary terms. Even ecosystem engineers evolve along with other inhabitants of their ecosystems, developing ways to coexist.

The human evolutionary line began about 7 million years ago in Africa. It took some 3 or 6 million years for protohumans to spread from there to Asia and then Europe. These early humans lived a hunting-gathering life, using a variety of stone tools to feed on easy-to-kill prey; they differed little from other primates trying to survive. But by 13,000 years ago, modern humans had become unlike any other species, having spread to all the continents and many islands across the globe.

Still, most human-environment interactions at this stage consisted of threats to human health and well-being that came from the environment, including injuries in fights or wars, periodic famine, vector-borne diseases, and accidents (Table I). Then, some 10,000 years ago, people began to domesticate plants and animals. Instead of searching for food, they began to produce food. Food production changed the course of human and environmental history. Domestication of plants and animals enabled people to adopt a sedentary lifestyle. People gathered food rather than searching for it; they began to live in crowded conditions, inadequate sanitation compounded the effects. From agriculture, civilization followed; and with it, cities, writing, engineering, and political empires.

In just 10,000 years, these developments led to 6 billion people on Earth, industrial societies, and a global economy founded on complicated technologies. Now the predominant human-environment interaction consists of threats to all four of the earth's environmental "spheres":

• Geosphere (lithosphere), the earth's crust and upper mantle, containing nonrenewable fossil fuels, minerals, and nutrients plants require. The activities of plants, animals, and microorganisms weather mineral soils and rocks, create organic soils, and alter erosion and sedimentation rates. Humans mine minerals, metals, and

New challenges are listed in the era they began; all continue through the present.

• Atmosphere, the thin envelope of gases that encircles the planet. Living systems maintain the earth’s atmosphere, its temperature, and the amount of water it contains by continually generating oxygen through photosynthesis, holding down atmospheric carbon dioxide, and changing the amount and forms of other gases. Humans release toxic chemicals into the air and alter the climate by raising the atmospheric concentration of greenhouse gases such as carbon dioxide and methane through the burning of fossil fuels in motor vehicles, electricity-generating plants, and airplanes.

• Hydrosphere, the earth’s liquid surface and underground water; its polar ice caps, oceanic icebergs, and terrestrial permafrost; and its atmospheric water vapor. Living systems alter the water cycle by modifying Earth’s temperature and the amount of water plants send into the atmosphere in a process called evapotranspiration. Humans build dams, irrigation canals, drinking-water delivery mechanisms, and wastewater treatment systems. They use water to generate electricity; they mine groundwater for farming and drinking; they alter the flows of surface waters for everything from transportation to gold mining; they drain wetlands to gain land area and abate waterborne diseases. Modern human interference in global climate is likely to alter the entire planetary water cycle.

• Biosphere, the earth’s living systems, which occupy a thin layer from the deepest oceans to the top of the highest mountains. Life on Earth emerged 3.9 billion years ago and has sustained itself through changes in form, diversity, and detail since then. No other known planet supports life. Like other predators, humans affect the populations of their prey, on a small scale millions of years ago and on much larger scales since. Thousands of years ago, humans hunted the large mammals of Australia and the Americas to the point where many became extinct. Humans have domesticated plants through agriculture and massively redistributed vegetation through cutting of forests, burning of grasslands, or land uses creating vast areas of desert. Human actions today have precipitated a spasm of extinctions rivaling five previous mass extinctions caused by astronomical or geological forces; each of these eliminated more than 70% of species then existing.

Yet despite today’s world-altering technologies and computer-generated virtual reality, humans are as dependent on their environments as other organisms are. History, not just ecology, is very clear on this point. From the Old Kingdom of Egypt more than 4000 years ago to the culture that created the huge stone monoliths on Easter Island between 500 and 1550 A.D. to the 1930s dust bowl of North America, civilizations or ways of life have prospered and failed by using and (mostly unwittingly) abusing natural resources.

In Old Egypt, the resource was the valley of the Nile,
The first step in dealing with the present impact of human activity is to correctly identify the nature of humanity's relationship with the environment and how human actions affect that relationship. Many people still see the environment as something people must overcome, or they regard environmental "needs" as something that ought to be balanced against human needs (for example, jobs versus the environment). Most people still see humans' relationship with the environment as a one-way street: the environment provides us with goods and services, and our job is to keep them这位us and services coming.

Thus, when asked to name humanity's principal environmental challenges, people usually think of running out of nonrenewable raw materials and energy, or about water and air pollution. Our environmental research and development institutions focus on ways technology can help solve each problem, such as fuel cells to provide clean, potentially renewable energy or scrubbers to curb smogstack pollution. Even when people worry about "biodiversity loss," they are primarily concerned with stopping species extinctions rather than with understanding the underlying losses leading up to species extinctions or the broader biological crisis that extinctions signal.

This perspective misses a crucial point: humanity has a two-way relationship with the biosphere. The reason pollution, energy use, extinction, and dozens of other human impacts are important is their larger impact on the biosphere. At this point in the planet's history, one species is compromising the earth's ability to support the living systems that evolved here over millions of years.

The systematic reduction in the earth's capacity to support life, termed biotic impoverishment, is thus the most important human-caused environmental impact. At best, the ethics of this impact are questionable; at worst, we are jeopardizing our own survival.

The connection between extinction and biotic impoverishment is intuitively obvious. By overharvesting fish, overcutting forests, overgrazing grasslands, or paving over land for cities, humans are clearly killing other organisms outright or eliminating their habitats, thereby driving species to extinction. But biotic impoverishment takes many forms besides extinction. It encompasses three categories of human impacts on the biosphere: (a) indirect depletion of living systems through alterations in physical and chemical environ-
The Many Faces of Biotic Impoverishment

1. Degradation of water (redistributed flows, depletion of surface and ground water, wetland drainage, organic enrichment, destruction and alteration of aquatic life.)
2. Soil depletion (destruction of soil structure, erosion, salinization, desertification, nutrient leaching, destruction and alteration of soil biota)
3. Chemical contamination (land, air, and water pollution from pesticides, herbicides, heavy metals, and toxic synthetic chemicals and atmospheric ozone depletion; kills, extinctions, biodiversity loss, bioaccumulation, hormone disruption, immunological deficiencies, reproductive and developmental anomalies, respiratory disease, intergenerational effects)
4. Altered biogeochemical cycles (alteration of the water cycle, nutrients enrichment, acid rain, fossil fuel emissions, particulate pollution, degradation of land and water biota and outbreaks of pests, pathogens, and red tides)
5. Global climate change (rising greenhouse gases, altered precipitation and airflow patterns, rising temperatures, effects on individual and community health and shifts among and within global ecosystems)

Direct depletion of nonhuman life

1. Overharvest of renewable resources such as fish and timber (depleted populations, extinctions, altered food webs)
2. Habitat fragmentation and loss (extinctions, biotic homogenization, emerging and reemerging pests and pathogens)
3. Biotic homogenization (extinctions and invasions)
4. Genetic engineering (homogenization of crops, antibiotic resistance, potential extinctions and invasions if genes escape, other unknown ecological effects)

Direct degradation of human life

1. Epidemics and emerging diseases (occupational hazards, asthma and other respiratory ills, pandemics, plagues, HIV/AIDS, malaria, tuberculosis, Lyme disease, antibiotic resistance, diseases of overnutrition, higher human death rates)
2. Loss of cultural diversity (genocide, ethnic cleansing, loss of cultural and linguistic diversity, loss of knowledge)
3. Reduced quality of life (environmental refugees, malnutrition and starvation, failure to thrive, poverty)
4. Environmental injustice (environmental discrimination and racism; economic exploitation; growing gaps between rich and poor individuals, segments of society, and nations; gender inequities; trampling of the environmental and economic rights of future generations)
5. Political instability (resource wars, civil violence especially under intransigent regimes, international terrorism, increased number of environmental refugees)
6. Cumulative effects (environmental surprises, increased frequency of “natural” catastrophes, “boom and bust” cycles, collapse of civilizations)

dry up wetlands, lakes, and inland seas. Our demands are outrunning supplies of this nonrenewable resource, and the scale of our transformations risks altering the planet’s water cycle.

Physical alterations to the planet’s waters, combined with massive industrial and residential pollution, have taken a heavy toll on nonhuman aquatic life. Ten percent of the world oceans’ coral reefs have died from pollution and other causes. Globally, the number of so-called oceanic dead zones, where there is little or no dissolved oxygen, tripled in the last 30 years of the 20th century. The biota of freshwater systems fares no better. A 4-year survey of the freshwater fishes inhabiting Malaysian rivers in the late 1980s found only 46% of the 266 known Malaysian species. Nearly 40% of North America’s freshwater fishes are at risk of extinction; two-thirds of freshwater mussels and crayfishes and one-third of amphibians that depend on aquatic habitats in the United States are rare or imperiled. Wetlands worldwide continue to disappear; the lower 48 United States lost 53% of its wetlands between the 1700s and mid-1980s. Such losses destroy major fish and shellfish nurseries, natural flood and pollution control, and habitat for countless plants and animals.

Humans now use 54% of the accessible water runoff on Earth, a figure that is likely to grow to 70% by 2025. By then, more than a third of the world’s population could suffer shortages of fresh water for drinking and irrigation. Groundwater aquifers in many of the world’s most important crop-producing regions are being drained faster than they can be replenished. Natural flood regimes, as in the Nile River basin, no longer spread nutrient-rich silt across floodplains to nourish agriculture; indeed, the High Dam at Aswan traps so much silt behind it that the Nile delta, essential to Egypt’s modern economy, is falling into the sea. In the past 30 years, the number of large dams on the world’s rivers grew more than seven times, to some 38,000 today. The huge Three Gorges Dam across China’s Yangtze River promises to create a 690-km serpentine lake behind it and displace 1.2 million Chinese citizens before its scheduled completion in 2009; the impact on the river’s fertile delta farming region and downstream estuaries has just begun to be assessed. Whole inland seas, such as the Aral Sea in Uzbekistan, are drying up because the streams feeding them have so little water. In addition to eliminating habitat for resident organisms, the seas’ drying is bringing diseases to surrounding human populations. Diseases caused by waterborne pathogens are making a comeback even in industrialized nations.

2. Soil Depletion

Hardly just “dirt,” soil is a living underground system that makes it possible for raw elements from air, water, and bedrock to be physically and chemically assembled, and reassembled with the aid of living macro- and microorganisms into the thin green shell of life above ground. Accumulated over thousands of years, soil cannot be renewed in any time frame useful to humans alive today, or even to their great-grandchildren. Humans degrade soils when they compact it, erode it, disrupt its organic and inorganic structure, turn it too salty for life, and cause desertification. Urbanization, logging, mining, overgrazing, altering soil moisture, air pollution, fires, chemical pollution, and leaching out of minerals all damage soils. Thanks to removal of vegetative cover, mining, agriculture, and other activities, the world’s topsoils are eroded by wind and water ten to hundreds of times faster than they are renewed (at roughly 1 ton per hectare per year). Soils constitute the foundation of human agriculture, yet agriculture, including livestock raising, is the worst culprit in degrading soils. Agricultural practices have eroded or degraded an area equal to 38% of present cropland. Besides topsoil erosion, the damage includes salting and water-logging of poorly managed irrigated lands, compaction by heavy machinery and the hooves of livestock, and pollution from excessive fertilizers, animal wastes, and pesticides.

Living, dead, and decomposing organic matter is the key to soil structure and fertility. Soil depleted of organic matter is less permeable to water and air and thus less able to support either aboveground plants or oxygen-dependent microbes. It’s the linkages between soil’s inorganic components and the soil biota (naturalist E. O. Wilson’s “little things that run the world”) that give soil its life-sustaining capacity. A clear-cut forest patch whose soil biota has been damaged beyond recovery can no longer sustain trees, no matter how many are planted, another clear-cut patch whose soil community is still functioning will support new tree growth. Destroying soil biota exerts a whole series of impoverishing biotic effects both below and above ground.

3. Chemical Contamination

In 1962 Rachel Carson’s landmark book Silent Spring alerted the world to the pervasiveness of synthetic chemicals produced since World War II. Some 75,000 synthetic chemicals are in use today. True to one company’s slogan, many of these have brought “better living
through chemistry,” providing new fabrics and lighter manufacturing materials, antibiotics, and life-saving drugs. But industrial nations have carelessly pumped chemicals into every medium. Chemicals directly poison organisms; they accumulate in physical surroundings and are passed up the food chain. Many chemicals travel the ocean and atmospheric currents to sites far from their source: sulfur emissions from the U.S. Midwest, for example, fall to earth again as acid rain in Europe, killing forests and so acidifying streams and lakes that they too effectively die. China’s burning of soft coal sends air pollution all the way to northwestern North America; the heavy haze hanging over China’s chief farming regions may be cutting agricultural production by as much as a third. Chlorofluorocarbons (CFCs), once widely used as refrigerants, have damaged the atmospheric ozone layer, which moderates how much ultraviolet radiation reaches the earth, and opened ozone “holes” over the Arctic and Antarctic. Chemicals ranging from prescription drugs flowing out of sewage plants to pesticides to heavy metals to cancer-causing by-products of countless manufacturing processes now lace the world’s water, soil, and air and the bodies of all living things, including humans. Carson’s book revealed the real danger of chemical pollution: we have not simply altered the chemistry of water, soil, and air but harmed the biosphere as well.

Although many of the most obviously deadly compounds were banned in the 1970s, they continue to impoverish the biosphere. Polychlorinated biphenyls (PCBs)—stable, nonflammable compounds once used in electrical transformers and many other industrial and household applications—accumulate and persist in soils and the food web. They are found in polar bears and arctic villages; they are implicated in reproductive disorders, particularly in such animals as marine mammals, whose long lives, thick fat layers where chemicals concentrate, and position as top predators make them especially vulnerable. The agricultural pesticide DDT, sprayed with abandon in the 1940s and 1950s, even directly on children, severely thinned wild birds’ eggshells. Populations of birds such as the brown pelican and bald eagle dropped precipitously by the 1970s but began to recover in the last decade of the 20th century. Chemicals cause cancer, disrupt hormonal systems, provoke asthma, and impair the functioning of immune systems. They have intergenerational effects, such as intellectual impairment in children whose mothers have eaten contaminated fish. What’s more, a half century of pesticide and antibiotic overuse has bred resistance to these chemicals among insects, plants, and microbes, prompting fears of new and reemerging scourges. The litany of chemicals’ effects on living things is so long that chemical pollution is humans’ environmental impact in most people’s minds; yet it is just one form of biotic impoverishment.

4. Altered Biogeochemical Cycles

All the substances found in living things, such as water, carbon, nitrogen, phosphorus, and sulfur, cycle through ecosystems in biogeochemical cycles. Human activities alter or have the potential to alter all these cycles. Sometimes the results stem from changing the amount or the precise chemistry of the cycled substance; in other cases, humans alter biogeochemical cycles by changing the biota itself.

Freshwater use, dams, and other engineering feats change the amount and rate of river flow to the oceans and increase evaporation rates, directly affecting the water cycle and indirectly impoverishing aquatic life. Direct human modifications of living systems also perturb the water cycle. In the tall “cloud forests” of redwoods in northern California or Douglas firs in the Pacific Northwest, the trees gather more moisture directly from the clouds than falls as rain. Among the effects of logging in such forests is a depletion of stream flows, which shifts the water cycle. In South Africa, European settlers supplemented the treeless native scrub, or fynbos, with such trees as pines and Australian acacias from similar Mediterranean climates. Because these trees are larger and thirstier than the native scrub, regional water tables have fallen sharply. Human activity has altered the global nitrogen cycle by greatly increasing the amount of nitrogen fixed from the atmosphere (combined into compounds usable by living things). The increase comes mostly from deliberate addition of nitrogen to soils as fertilizer but also as a by-product of the burning of fossil fuels. Agriculture, livestock raising, and individual yard maintenance chronically add tons of excess nutrients, including nitrogen and phosphorus, to soils and water. The additions are often invisible; their biological impacts are often dramatic. Increased nutrients in coastal waters, for example, trigger blooms of toxic dinoflagellates, the algae that cause red tides, fish kills, and tumors and other diseases in varied sea creatures. When huge blooms of algae die, they fall to the seafloor, where their decomposition so robs the water of oxygen that fish and other marine organisms can no longer live there. With nitrogen concentrations in the Mississippi River two to three times as high as they were 30 years ago, a gigantic dead zone forms in the Gulf of Mexico.
every summer; it covered a record 20,020 square kilometers in the summer of 1999. The burning of fossil fuels is radically altering the carbon cycle, primarily by greatly increasing the atmospheric concentration of carbon dioxide. With other greenhouse gases, such as methane and oxides of nitrogen, carbon dioxide helps keep the earth's surface at a livable temperature and drives plant photosynthesis, but since the industrial revolution, atmospheric carbon dioxide concentrations have risen 30% and are now widely thought to be disrupting the planet’s climate.

5. Global Climate Change

The Intergovernmental Panel on Climate Change (IPCC), comprising 2300 of the world’s preeminent atmospheric scientists, had concluded by 1995 that humans have caused at least part of the atmospheric warming observed globally since the beginning of the 20th century. The concentrations of heat-trapping gases in the atmosphere are at their highest level in more than 200,000 years. The 20th century is the Northern Hemisphere has been described as the warmest of the past millennium; the 1990s ranked as that century’s warmest decade.

Higher global temperatures precipitate a whole series of effects, making the study of climate change, and of humans’ role in it, complex and controversial. Spring now arrives one week earlier in the Northern Hemisphere than in the past. Each year’s growing season starts earlier, and seasonal temperature patterns are also shifting, making the weather seem more unpredictable than ever. Unusually warm or cold winters, massive hurricanes such as those that devastated North Carolina in late summer 1999, and weather-related damage to human life and property are all predicted to increase with global warming. Weather-related damage totaled $92 billion in 1998, exceeding the total for the entire decade of the 1980s, even after adjusting for inflation.

Rising carbon dioxide concentrations may enhance plant photosynthesis and growth where other nutrients are not limiting. Rising temperatures may shift the ranges of many plants and animals, shifting the composition and distribution of the world’s biomes. The resulting disruptions to habitats will have far-reaching implications not only for the displaced plants and animals but also for the goods and services humans depend on from living systems.

B. Direct Depletion of Nonhuman Life

From their beginnings as hunter-gatherers, humans have become highly efficient, machine-aided ecosystem engineers and predators. We transform the land so it produces what we need or want; we harvest the oceans in addition to reaping our own fields; we cover the land, even agricultural land, with sprawling cities. All these activities directly affect the ability of other life-forms to survive and reproduce. We deplete nonhuman life by eliminating some forms and favoring others; the result is a loss of genetic, population, and species diversity. We are irreversibly homogenizing life on Earth, in effect exercising an ‘unnatural selection’ that is erasing the diversity generated by millions of years of evolution by natural selection. One species is now determining which other species will survive, reproduce, and thereby contribute the raw material for future evolution.

1. Overharvest of Renewable Resources

In the 1930s, so many sardines were scooped from the waters off Monterey’s Cannery Row that the population collapsed, taking other sea creatures and human livelihoods with it; the species has still not recovered fully. According to the U.S. National Marine Fisheries Service, nearly 80% of commercially valuable fish of known status were overfished or ‘fished to their full potential’ by 1993. Atlantic commercial fish species at their lowest levels in history include runas, marlins, cod, and swordfish. Overfishing not only depletes the target species but changes the whole structure of marine food webs.

Marine mammals, including whales, seals, sea lions, manatees, and sea otters, were so badly depleted by human hunters that one species, Steller’s sea cow (Hydrodamalis gigas), went extinct; many other species almost disappeared. In the 19th century, Russian fur traders wiped out sea otters (Enhydra lutris) along the central California coast; with the otters gone, their principal prey, purple sea urchins (Stronglyocentrotus purpuratus) overran the offshore forests of giant kelp (Macrocystis pyrifera), decimating the kelp fronds and the habitat they provided for countless other marine creatures, including commercially harvested fishes. Thanks to three decades of protection, most marine mammal populations are slowly rebounding—only to face food shortages following disruptions in regional marine food webs due to fishing, changing oceanic conditions, and contamination.

Timber harvest has stripped vegetation from the Amazon rain forests to mountainsides on all continents, diminishing and fragmenting habitat for innumerable
forest and stream organisms, eroding soils, worsening floods, and contributing significantly to global carbon dioxide emissions. In the Northern Hemisphere, only 10% remains of old-growth temperate rain forests. The uniform stands of trees usually replanted after logging do not replace the diversity lost with the native forest, any more than monocultures of corn replace the diversity within native tallgrass prairies.

2. Habitat Fragmentation and Loss

Human land use inevitably damages or destroys habitat for some living thing. But satellite-mounted remote-sensing instruments over the past two decades reveal transformations of a scale unimaginable in centuries past. At one extreme, row-crop agriculture or urban-industrial areas occupy only 10 to 15% of the earth's land surface; pastureland occupies another 6 to 8%. At the other extreme, every alteration of the land alters the physical, chemical, and biological surroundings of anything living there. Estimates of the share of land wholly transformed or degraded by humans fall at around 50%. Landscapes that have not been entirely converted to human use have been cut into fragments. In Song of the Dodo, writer David Quammen likens our actions to starting with a fine Persian carpet and then slicing it nearly into 56 equal pieces; we still have the same square footage but not 36 nice Persian rugs, only ragged, nonfunctional fragments.

Our roads, farms, cities, feedlots, and ranches either destroy or fragment the habitats of most large carnivorous mammals. Mining and oil drilling damage the soil, remove vegetation, and pollute marine areas. Grazing compacts soil and sends silt and manure into streams, remove vegetation, and pollute marine areas. Grazing compacts soil and sends silt and manure into streams, where they harm stream life. Habitat damage may lead directly to extinction, or it may isolate organisms in ways that make them extremely vulnerable to natural disturbances, climate change, or further human disturbance.

3. Biotic Homogenization

"The one process now going on that will take millions of years to correct," writes E. O. Wilson, "is the loss of genetic and species diversity by the destruction of natural habitats. This is the folly our descendants are least likely to forgive us." Both deliberately and unwittingly, humans are rearranging the earth's living components, reducing diversity and homogenizing biotas around the world. The present, continuing loss of genetic diversity, of populations, and of species vastly exceeds background rates. At the same time, our global economy is transporting species worldwide at unprecedented scales.

The globe is now experiencing its sixth mass extinction, the largest since the fall of the dinosaurs 65 million years ago; present extinction rates are thought to be on the order of 100 to 1000 times those before people dominated the earth. Many of the world's bird species have been driven to extinction by humans, especially on oceanic islands. According to a survey by the World Conservation Union, at least one of every eight plant species is threatened with extinction. Although mammals and birds receive the most attention, massive extinctions of plants, which form the basis of the biosphere's food webs, undermine life-support foundations. Some scientists are calling extinction "the worst biological tragedy," but extinction too is but another symptom of global biotic impoverishment.

Ever since they began to spread over the globe, people have transported other organisms with them, sometimes for food, sometimes for aesthetic reasons, and most often inadvertently. With the mobility of modern societies and today's especially speedy globalization of trade, the introduction of alien species has reached epidemic proportions, causing some scientists to label it "biological pollution." Aliens—zebra mussels (Dreissena polymorpha) and tamarisks, or saltcedar (Tamarix spp.), in North America; the Red Sea jellyfish Rhopilema nomadica and the common aquarium alga Caulerpa taxifolia now choking the Mediterranean Sea; and Leidy's comb jelly (Mnemiopsis leidyi) of northeastern America in the Black Sea, to name just a few—are present everywhere, and they usually thrive and spread at the expense of native species. On many islands, for example, more than half the plant species are not native, and in many continental areas, the figure reaches 20% or more. Such alien invasions cause extinctions and, when added to other extinctions and the deliberate monocultures of agricultural crops, worsen biotic homogenization. Introduced species are fast catching up with habitat loss and fragmentation as the major engines of ecological deterioration.

4. Genetic Engineering

Humans have been manipulating their crop plants and domesticated animals for 10,000 years or so—selecting seeds or individuals, breeding, and cross-breeding. The goal was something better, bigger, tastier, harder, or all of the above; success was sometimes elusive, but the result was crop homogenization. Of the myriad strains of potatoes domesticated by South American cultures, for example, only one was accepted and cultivated when potatoes first made it to Europe. The new crop made it possible to feed more people from an equivalent area of land and initially staved off malnutrition. But the...
strain succumbed to a fungal potato blight in the 1880s; had more than one strain been cultivated, the tragic Irish potato famines might have been averted.

In the last few decades of the 20th century, people began to manipulate genes directly using the tools of molecular biotechnology, even cloning sheep and cows from adult body cells. U.S. farmers routinely plant their fields with corn whose genetic material incorporates a bacterial gene resistant to certain pathogens. More than 40 genetically altered crops have been approved for sale to U.S. farmers since 1992, with genes borrowed from bacteria, viruses, and insects; worldwide, upward of 40 million hectares are planted with genetically modified crops. Biotechnologists see this new-millennium green revolution as finally solving world hunger. But other scientists worry about unknown human and ecological health risks; these concerns have stirred a deep scientific debate, akin to the debate over pesticides in Rachel Carson’s time.

One worrisome practice is plant genetic engineers’ technique of attaching the genes they want to introduce into plants to an antibiotic-resistance gene. They can then easily select those plants that have acquired the desired genes by treating them with the antibiotic, which kills any nonresistant plants. Critics worry that the antibiotic-resistant genes could spread to human pathogens and worsen an already growing antibiotic-resistance problem. Another threat comes from allergies humans might have or develop in response to genetically modified foods.

Supporters of genetic engineering believe that genetically altered crops pose few ecological risks. But studies in the late 1990s indicated that pollen from genetically engineered “Bt corn” can kill monarch butterfly caterpillars. It is a strain of bacteria that has been used since the 1980s as a pesticidal spray; its genes have also been inserted directly into corn and other crops. Studies in radishes, sorghum, canola, and sunflowers found that genes from an engineered plant can jump to wild relatives through interbreeding. The fear is that a gene confering insect or herbicide resistance might spread through wild plants, creating invasive superweeds, which could potentially lower crop yields and further disrupt natural ecosystems.

Great economic and environmental benefits are claimed for the products of biotechnology: higher yields, lower synthetic pesticide and herbicide use, increased farmer profits. But so far the benefits have not always materialized, and growing consumer and scientific concern may slow the spread of genetically modified crops, at least in the developed world.

C. Direct Degradation of Human Life

Human biotic impacts are not confined to other species; human cultures themselves have suffered from the cascading indirect and direct impacts humans exert on the rest of nature. Over the past hundred years, human technology has been a two-edged sword with regard to public health. Wonder drugs controlled common pathogens at the same time that natural selection strengthened those pathogens’ ability to resist the drugs. Reservoirs in the tropics made water supplies more reliable for humans but also created ideal environments for human parasites. Industrialization exposed human society to a remarkable array of toxic substances.

Though “man’s inhumanity to man” has been both fact and the subject of discourse for thousands of years, the discussions have mostly been removed from any environmental context. Few people today regard social ills as “environmental impacts” or humans as part of a “biota.” But diminished societal well-being—whether manifest in high death rates or poor quality of life—shares many of its roots with diminished nonhuman life as a form of biotic impoverishment.

1. Epidemics and Emerging Diseases

The interface between the environment and human health is the core of the discipline known as environmental health. Among the environmental challenges to public health are the direct effects of toxic chemicals; occupational health threats, including exposures to hazardous materials on the job; and sanitation and hazardous waste disposal. Exploitation of nonrenewable natural resources—including coal mining (causing black lung disease), rock quarrying or other mining operations (causing silicosis), and petroleum extraction and refining—often chronically impairs workers’ health and shortens their lives. Farmworkers around the world suffer long-term ills from high exposures to pesticides and herbicides. Partly because of increased air pollution, asthma rates are rising, particularly in big cities. Synthetic volatile solvents are used in products from shoes to semiconductors, producing lung diseases and toxic wastes. Nuclear weapons production starring in World War II, and the associated contamination, have been linked to a variety of diseases.

Infectious diseases have challenged human populations throughout history, playing a significant role in their evolution and cultural development. The 20th century brought major successes in eradicating such infectious diseases as smallpox, polio, and many waterborne illnesses. But toward the century’s end, emerging
and reemerging diseases were again reaching pandemic proportions. Human migrations have been the main source of epidemics throughout history, but environmental and social changes resulting from human activities are accelerating pathogen traffic. Infectious diseases thought to be on the wane—including tuberculosis, malaria, cholera, diphtheria, leptospirosis, encephalitis, and dengue fever—began a resurgence. In addition, seemingly new scourges—Ebola virus, hantavirus, HIV/AIDS, legionnaires’ disease, and Lyme disease—are also spreading, often, it appears, from animal hosts to humans as people encroach further upon previously undisturbed regions.

Especially in highly developed countries such as the United States, diseases of affluence and overconsumption are also taking a toll. Heart disease is the number one cause of death in the United States; overnutrition and obesity due to sedentary, technology-driven lifestyles, particularly among children, is chronic and rising. One estimate put the share of U.S. children considered overweight or obese at one in four.

2. Loss of Cultural Diversity

Although not conventionally regarded as elements of biodiversity, human languages, customs, agricultural systems, technologies, and political systems have evolved out of specific regional environments. Like other organisms’ adaptive traits and behaviors, these elements of human culture constitute unique natural histories adapted, like any natural history, to the biogeographical context in which they arose. Yet unique indigenous human cultures, including knowledge of local medicines and geographically specialized economies, are disappearing even more rapidly than the natural systems that nurtured them.

Modern technology, transportation, and trade are moving the world toward a globalized culture, thereby reducing human biological and cultural diversity. Linguists, for example, are predicting that at least half of the modern world’s 6000 languages will become extinct in the twenty-first century. Indigenous knowledge and practices are dwindling fast with the spread of Euro-American culture. This loss of human biodiversity is in every way as troubling as the loss of nonhuman biodiversity.

3. Reduced Quality of Life

Human activities that degrade environmental conditions threaten not only the biosphere but also humans’ own quality of life. Many sectors of society now recognize this link. In 1990 the United Steelworkers of America endorsed a report saying “We cannot protect steelworkers jobs by ignoring environmental problems” and “the greatest threat to our children’s future may lie in the destruction of their environment.” Independent of race or economic class, declining quality of life is manifest in both the increased incidence of asthma in the United States caused by environmental contaminants and the high disease rates in the former Soviet Bloc after decades of unregulated pollution. Even with explicit legal requirements that industries release information on their toxic emissions, many people throughout the world still lack both information and the decision-making power that would give them any control over the quality of their lives.

Food availability, which depends on environmental conditions, is a basic determinant of quality of life. Yet according to the World Health Organization, roughly half the population in all nations suffers from two forms of poor nutrition: undernutrition and overnutrition. A swollen abdomen is now a symptom shared by malnourished children, who lack calories and protein, and overweight residents of the developed world, who suffer clogged arteries and heart disease because of eating too much food.

Deeply concerned about the degraded environment and resulting quality of life in his homeland, Ogoni activist Ken Saro-Wiwa stated, shortly before he was executed by the Nigerian government in 1995, “The environment is man’s first right. Without a safe environment, man cannot exist to claim other rights, be they political, social, or economic.” Environmental degradation and desperate living conditions have spawned a new kind of refugee: the number of international environmental refugees exceeded the number of political refugees around the world for the first time in 1999. Environmental refugees—the homeland of which is lost forever—were flooded from dam building, extraction of mineral resources, desertification, and unjust policies of national and international institutions. Such degradation preempts many fundamental human rights, including the rights to health, livelihood, culture, privacy, and property.

4. Environmental Injustice

Making a living from nature’s wealth has consistently opened gaps between haves and have-nots, between those who bear the brunt of environmental damage to their home places and those who do not, and between the rights of people alive now and those of future generations; these disparities too are part of biotic impoverishment. Inequitable access to “man’s first right”—a
healthy local environment—has come to be known as environmental injustice.

Environmental injustices, such as institutional racism, occur in industrial and nonindustrial nations. Injustice can be overt, as when land-use planning sites landfill, incinerators, and hazardous waste facilities in minority communities, or when environmental agencies levy lower fines for hazardous waste violations that are lower in minority communities than in white communities. Less overt, but no less unjust, is the harm done to one community when unsound environmental practices benefit another, as when clear-cut logging in the highlands of northwestern North America benefits logging communities while damaging the livelihoods of lowland fishing communities touched by debris flows, sedimentation, and downstream flooding.

The plight of the working poor and the disparities between rich and poor are also examples of biotic impoverishment within the human community. According to the United Nations Research Institute for Social Development, the collective wealth of the world’s 358 billionaires equaled the combined income of the poorest 2.4 billion people in 1994. In the United States during the last decade of the twentieth century, the incomes of poor and middle-class families stagnated or fell, despite a booming stock market. The Center on Budget and Policy Priorities and the Economic Policy Institute pointed out that, between 1988 and 1998, earnings of the poorest fifth of American families rose less than 1%, while earnings of the richest fifth jumped 13%.

Despite great advances in the welfare of women and children over the past century, poverty still plagues both groups. Children from impoverished communities, even in affluent nations, suffer from the lethargy and impaired physical and intellectual development known as failure to thrive. Poverty forces many children to work the land or in industrial sweatshops; lack of education prevents them from attaining their intellectual potential. This impoverishment in the lives of women and children is as much a symptom of biotic impoverishment as are deforestation, invasive alien organisms, or species extinctions.

The creation of a “third world” to supply raw materials and labor to the dominant European civilization after 1300—and the resulting schism between today’s developed and developing nations—is perhaps the grossest example of human and environmental domination leading to continued injustice. Exploitation of poor countries and their citizens by richer, consumer nations (as well as by the governments of developing nations themselves) persists today in agriculture, wild materials harvesting, and textile and other manufacturing sweatshops. In the mid-1990s, industrial countries consumed 86% of the globe’s aluminum, 81% of its paper, 80% of its iron and steel, 75% of its energy, and 61% of its meat; they are thus responsible for most of the environmental degradation associated with producing these goods. Yet most of the actual degradation takes place in poorer, developing countries.

Ironically, local environmental injustice often arises in the name of national development. Locals resist projects that seem socially disruptive or ecologically unsustainable while governments push them as potential boons to the national economy. China’s Three Gorges Dam presents one example; another is the governments-backed exploitation, fought by Saro-Wiwa, of Ogoniland’s oil reserves in southern Nigeria by the Shell Petroleum Development Corporation. After Saro-Wiwa’s execution, the Ogoni were left, without a voice, to deal with a scarred and oil-polluted homeland.

Governments of developing nations are starting to demand a share of profits made from biological resources within their borders, including pharmaceuticals from plants and animals or new strains bred from local crop varieties. Nature’s “free wealth” is now commonly viewed as a “genetic resource,” the raw material for the biotechnology age like fossil fuels or minerals for the industrial age. Still, profits tend to flow to the elite, wealthy classes of both developing and developed nations while indigenous groups remain marginalized.

Little by little, so-called community-based conservation and development initiatives are being mounted by local citizens worldwide to combat these injustices. And one might contend that all efforts to protect the biosphere constitute a fight for the rights of future generations to an environment that can support them.

5. Political Instability

It was only during the last two decades of the 20th century that environmental issues found a place on international diplomatic agendas, as governments began to see threats to political security in an environmentally destabilized world. The 1987 Montreal Protocol on Substances That Deplete the Ozone Layer, which forced countries to curb their use of CFCs and other ozone-destroying chemicals, was an example of governments, nongovernmental organizations, and industry successfully working together to safeguard part of the environmental commons. More often, diplomacy stalled in conflicts over natural resources: arguments over water rights held up Israeli-Palestinian peace agreements; fights over fish erupted between Canada and the United States, Spain, and Portugal.
Scholars, including Norman Myers and Thomas Homer-Dixon, began calling attention to the links among growing populations, environmental scarcity and degradation; environmental injustice; and civil violence, including urban unrest. Myers noted that we cannot dispatch the military to turn back the advancing deserts, rising seas, or the greenhouse effect. Homer-Dixon and others pointed out that nations with high population growth, rising urbanization and unemployment, and depleted resources are becoming increasingly hard to govern except by tyrannical means. Perversely, the laudable goals of democracy and increased human rights can lead to civil riots in such nations as India, Pakistan, Indonesia, and China. Environmental and economic injustices worldwide leave no nation immune to this type of threat.

6. Cumulative Effects
If scientists have learned anything about the factors leading to biotic impoverishment, they have learned that the factors' cumulative effects can take on surprising dimensions. The multiple stresses of global climatic cycles such as El Niño–Southern Oscillation, natural disasters like droughts or floods, biotic impoverishment, and political instability have changed the course of history. Civilizations as far-flung as ancient Egypt, Peru, Easter Island, and the American Southwest prospered and collapsed because of unwise management of their environments. The city of Ubar, built on desert sands, literally disappeared into the sinkhole created by drawing too much water out of its great well. In modern Sahelian Africa, a combination of well digging and improved medical care and sanitation led to a threefold population increase; sedentary ways, heavy taxes imposed by a colonial government, and an impoverished people took the place of a nomadic culture evolved within the desert's realities.

During the last decade of the 20th century, numerous natural disasters befell nations around the world: massive flooding along the Mississippi River; devastating hurricanes in the Caribbean and southeastern United States; catastrophic landslides and floods in Honduras, China, and Venezuela; and destructive earthquakes in Turkey and Taiwan. Neither the rains nor the earthquakes were caused principally by human activity, but the cumulative effects of human land uses and management practices—from dikes separating the Mississippi from its floodplain to hog and poultry farms in North Carolina to clear-cut logging in Honduras to crowded cities in Turkey and Taiwan—made the disasters much worse in loss of human life and property.

IV. ROOT CAUSES OF HUMAN IMPACT
The ultimate cause of humans' massive environmental impact is our reproductive and consumptive behavior, which has given us spectacular success as a species. The very things that enabled humans to thrive in nearly every environment have magnified our impacts on those environments, and the technological and political steps we take to "mitigate" our impacts often worsen them. There are simply too many of us, we take too much from the natural world, and we ask it to absorb too much waste.

A. Fragmented Worldviews, Fragmented Worlds
For most of human history, people remained tied to their natural surroundings. Even as agriculture, writing, and technology advanced, barriers of geography, language, and culture kept humans a diverse lot, each group depending on mostly local and regional resources for survival. Their worldviews, and resulting economies, reflected this dependency. In northwestern North America, for example, a native economy centered on the abundance of salmon began to develop about 3000 years ago. At its core was the concept of the gift and a belief system that treated all parts of the earth—animate and inanimate—as equal members of a community. In this and other ancient gift economies, a gift was not a possession that could be owned; rather, it had to be passed on, creating a cycle of obligatory returns. Individuals or tribes gained prestige through the size of their gifts, not the amount of wealth they accumulated.

This system coevolved with the migratory habits of the salmon, which moved en masse upriver to spawn each year. Because the Indians viewed salmon as equals to themselves, killing salmon represented a gift of food from salmon to people. Fishers were obligated to treat salmon with respect or risk losing this vital gift. The exchange of gifts between salmon and humans—food for respectful treatment—minimized waste and the chance of overharvesting and ensured a continuous supply of food. Further, the perennial trading of gifts among the people effectively redistributed the natural wealth brought each year by fluctuating populations of migrating fish, leveling out the boom-and-bust cycles that usually accompany reliance on an uncertain resource.

In modern times, the gift economy has gone entirely, along with the egalitarian worldview that accompanied...
it. We now have a redistributive economy tied not to an exchange of gifts with nature but to the exploitation of nature and to the technologies that enhance that exploitation. Nature became a resource for humans rather than an equal to humans. In economic terms, natural resources fell under the heading of ‘land’ in an economic trinity comprising three factors of production: land, labor, and capital. Land and resources, including crops, became commodities, expendable or easily substitutable forms of capital, whose value was determined solely by their value in the human marketplace.

In 1776 Adam Smith published his famous Inquiry into the Nature and Causes of the Wealth of Nations, in which he argued that society is merely the sum of its individuals, that the social good is the sum of individual wants, and that markets (the “invisible hand”) automatically guide individual behavior to the common good. Crucial to his theories was division of labor and the idea that all the factors of production were freely mobile; his mechanistic views created an economic rationale for no longer regarding individuals as members of a community linked by moral, social, and ecological bonds.

About the same time, fueling and fueled by the beginnings of the industrial revolution, the study of the natural world was transforming itself into modern physics, chemistry, geology, and biology. Before the mid-19th century, those who studied the natural world—early 19th-century German biogeographer Baron Alexander von Humboldt and his disciple Charles Darwin among them—took an integrated view of science and nature, including humans. For von Humboldt, understanding interdependence was the “noblest and most important result” of scientific inquiry. But this integrated natural philosophy was soon supplanted by more atomistic views, which fit better with industrialization.

Mass production of new machines relied on division of labor and interchangeable parts. Like automobiles on an assembly line, natural phenomena too were broken down into their supposed component parts in a reductionism that has dominated science ever since. Rushing to gain in-depth, specialized knowledge, science and society lost sight of the need to tie the knowledge together. Disciplinary specialization replaced integrative scholarship.

Neoclassical economics, which arose around 1870, ushered in the economic worldview that rules today. A good’s value was no longer tied to the labor required to make it but derived instead from its scarcity. A good’s price was determined only by the interaction of supply and demand. As part of “land,” natural resources therefore became part of the human economy, rather than the material foundation that makes the human economy possible. Because of its doctrine of infinite substitutability, neoclassical economics rejects any limits on growth; forgotten are the classical economic thinkers and contemporaries of von Humboldt, including Thomas Malthus and John Stuart Mill, who saw limits to the growth of human population and material well-being.

B. Too Many and Too Much

In October 1999, the global human population reached 6 billion. It doubled from 3 billion to 6 billion in about 40 years—before most post–World War II baby boomers even reached retirement age. From the appearance of Homo sapiens about half a million years ago, it took humans until 1804 to reach their first billion, 123 years to double to 2 billion, and 33 years to achieve 3 billion. With fertility rates declining in developed countries, China, and some developing countries where women are gaining education and economic power, and with pandemics like AIDS claiming more lives, the United Nations predicts that world population will reach 8.9 billion by 2030. Lined up one by one, the world’s 6 billion people would stretch nearly to the moon; jammed together in a crowd, they would just fit into the state of Texas.

But these 6 billion people consume far more resources than can be produced by a piece of earth the size of Texas. As already noted, humans appropriate about 40% of global plant production, 54% of the earth’s freshwater runoff, and enough of the ocean’s bounty to deplete or nearly extinguish two-thirds of the world’s major marine fisheries. In energy terms, a human’s food consumption is about 2500 to 3000 calories a day, about the same as that of a common dolphin. But with all the other energy and materials humans use, the rise in global per capita energy and material consumption has soared even faster than population growth in the past 40 years. Mostly in the form of fossil fuels, North Americans consume six times as much energy as the average human. Now, instead of coevolving with a natural economy, global society is coevolving with fossil fuels and the American Dream.

V. MEASURING ENVIRONMENTAL IMPACTS

For most of the 20th century, environmental indicators tracked primarily two classes of information: counts of
administrative activities in support of environmental protection and the supply of products to people. Counting bureaucratic achievements—such as the numbers of environmental laws passed, permits issued, enforcement actions taken, or treatment plants constructed—focuses on actions rather than on the results of those actions. Ultimately such counts provide only limited information about real environmental status and trends. Resource managers concentrate on resource supply. Water managers, for example, measure “water quantity,” allocating water to domestic, industrial, and agricultural uses and rarely reserving any to sustain aquatic life or to protect scenic and recreational values. Foresters, farmers, and fishermen count board-feet of timber, bushels of grain, and tons and thousands of fish harvested. All these measures keep track of commodity production, not broader environmental quality. Even biologists’ counts of threatened and endangered species—which would seem to measure biotic impoverishment directly—still focus narrowly on biological parts, not ecological wholes. Enumerating threatened and endangered species is just like counting any other commodity, reinforcing humanity’s view that we know which parts of the biota are important or valuable.

Society needs to use to better effect the environmental measures it has had (Table III). It particularly needs objective measures more directly tied to the condition, or health, of the environment so that people can judge whether their actions are compromising that condition. Such measures should be quantitative yet easy to understand and communicate; they should be cost-effective and applicable in many circumstances. Unlike narrow criteria tracking only commodity or extinction numbers, they should provide reliable signals about status and trends in ecological systems. Ideally, effective indicators should describe the present condition of a place, document change, diagnose its cause, and predict what is likely to happen. They should reveal not only risks from present activities but also potential benefits from alternative management decisions.

Most important, these indicators should, either singly or in combination, give information explicitly about living systems. Measurements of physical or chemical factors can sometimes act as surrogates for direct biological measurements, but only when the connection between those measures and living systems is clearly understood. Too often we make assumptions—when water managers assume that chemically clean water equals a healthy aquatic biota, for example—that turn out to be wrong and fail to protect living systems.

As environmental concerns grow more urgent, several new measurements aim to direct the public’s attention to the value of living things. Using the value system best understood by the people and institutions driving the global economic engine, some researchers assign standard monetary amounts to the goods and services humans derive from nature. A calculation by Robert Costanza and his colleagues puts the average total monetary value of natural capital and ecological services in 16 biomes at US$33,000 billion per year—an amount exceeding the gross global product. Another study, by ecologist David Pimentel and his colleagues, calculated separate values for specific biological services, such as soil formation, crop breeding, or pollination; by summing these figures, these researchers estimate the total economic benefits of biodiversity for the United States at $319 billion, for the world at $2928 billion—in other words, 5 and 11% of the gross national and gross global products, respectively. Still another of Pimentel’s analyses reports that the approximately 50,000 nonnative species in the United States cause major environmental damage and reparation costs amounting to $137 billion a year. Though this monetary approach does not create a comprehensive indicator of environmental quality, it certainly points out that ecological values ignored by the global economy are very high.

Another accounting approach, pioneered by Canadian landscape planners Mathis Wackernagel and William Rees, translates humans’ impact on nature, particularly resource consumption, into a metaphorical “ecological footprint.” Researchers estimate the amount of land and water area required by a city, town, nation, or other human community to produce consumed resources and absorb the generated wastes; they then compare the physical area occupied by a city or country with the area required to supply that city or country’s needs. The 29 largest cities of Baltic Europe, for example, appropriate areas of forest, agricultural, marine, and wetland ecosystems that are at least 565 to 1130 times larger than the areas of the cities themselves. National ecological footprints range from a high of 10.3 hectares per person for the United States to 0.5 hectares per person for Bangladesh. Thirty-four of 52 nations are now operating under ecological deficits; that is, their material standards are subsidized by exploiting other nations’ natural capital.

Raising all 6 billion people on Earth at the start of the 21st century to living standards, and their ecological footprints, equal to those in the United States would require an additional two planets. Clearly, humans are consuming more resources, and discarding more waste, than the earth’s living systems can produce or absorb in a given time period. This gap is the global sustainability gap the world now faces.
### Indirect depletion of living systems through alterations in physical and chemical environments

1. Degradation of water (chemical contaminant concentrations, river flows, rainfall, runoff)
2. Soil depletion (erosion rates, desertification rates, salt accumulation in soils)
3. Chemical contamination (pollutant and toxic emissions, pollutant and toxic concentrations in air, water, soil, and living organisms)
4. Altered biogeochemical cycles (river flows and lake levels, amount of nutrients going into water bodies, or nutrient loading, nutrient concentrations in water bodies, chlorophyll concentrations reflecting nutrient-triggered algal blooms, oxygen depletion in water bodies, trophic status of lakes, changes in air and soil chemistry, atmospheric greenhouse gas concentrations)
5. Global climate change (atmospheric greenhouse gas concentrations, change in atmospheric temperatures, distribution and intensity of severe storms or droughts)

### Direct depletion of nonhuman life

1. Overharvest of renewable resources such as fish and timber (tons of fish harvested, fish population "escapement," hatchery fish released and recovered, board-feet of timber harvested, forest regrowth rates, "stumpage," or standing timber, ecological footprints)
2. Habitat fragmentation and loss (area of forest or wetland habitats remaining, landscape connectivity, rates of habitat destruction)
3. Biotic homogenization (number of extinct, threatened, and endangered taxonomic groups, spread of nonindigenous species, local or regional diversity, damage and repair costs of invasions or extinctions, major shifts in species distributions)
4. Genetic engineering (diversity among cultivated crop strains, genetic diversity within strains, escape of genetically engineered organisms or traits to wild populations)

### Direct degradation of human life

1. Epidemics and emerging diseases (death and disease infection rates, or mortality and morbidity, geographic spread of diseases, recovery rates, frequency and spread of antibiotic and other drug resistance)
2. Loss of cultural diversity (extinction of languages, disappearance of cultures)
3. Reduced quality of life (population size and growth, changes in death rates or average life spans, infant mortality rates, teen pregnancy rates, number of chronically malnourished individuals, starvation rates, literacy rates, rates of stress and other diseases of affluence, length of work week, child or other forced labor, employment shifts by economic sector)
4. Environmental injustice (string of toxic waste dumps or waste emissions relative to residents communities, economic exploitation of certain groups, worker strikes, wage and income gaps, unemployment rates for different economic sectors)
5. Political instability (frequency of domestic and international strife, environmental terrorism rates, number of environmental refugees, ethnic "cleansing")
6. Cumulative effects (frequency of "rare" natural disasters, costs of weather-related property damage, human death tolls, government subsidies of environmentally destructive activities such as fishery overcapitalization, below-cost timber sales, water projects, and agricultural supports, replacement costs for ecological services, pricing that reflects environmental costs, "green" taxes, use of polyvalent practices, number of organic farms)

*These indicators have been or could be used to monitor status and trends in environmental quality, including dimensions of biotic impoverishment. Without a full spectrum of indicators, however, and without coupling them to direct measures of biological condition, only a partial or segmented view of environmental quality (the degree of biotic impoverishment) will emerge.

A few indexes have integrated economic, environmental, and human community indicators into a general measure of sustainability. The index of environmental trends for nine industrialized countries incorporates ratings of air, land, and water quality; chemical and waste generation; and energy use since 1970. By its rankings, environmental quality in the United States has gone down by 22% while Denmark has declined by 11%. Social scientists Herman Daly and John Cobb developed an index of sustainable economic welfare that adjusts the United States' gross national product by factoring in environmental good things and factoring out environmental bad things. Public expenditures on education, for example, are weighted as "goods" while costs of pollution cleanup, depletion of natural resources, and treating environmentally related illnesses are counted as "bads." Instead of showing continual growth as gross national product does, the index of sustainable economic welfare has remained nearly unchanged over three decades.
Such approaches offer important insights into the dangers of local and global resource consumption and consumerism and paint a clearer picture than ever before of humans’ domination of the earth and the biosphere. But the accounting systems are still human centered. They still do not measure the condition of the biosphere itself. We may know that biodiversity’s services are worth huge sums of money and that our hometown’s ecological footprint is much bigger than our town, but how do we know whether specific actions damage living systems or that other actions benefit them? How do we know if aggregate human activity is diminishing life on Earth? To answer this question, we need direct measures of the condition of living systems.

More comprehensive than monetary or footprint analyses, biological assessment directly measures the attributes of living systems to determine the condition of a landscape. The very presence of living systems—sea palms on the California coast, salmon in Pacific Northwest waters, monk seals in the Mediterranean Sea—says that the conditions those organisms need to survive are also present. A biota is thus the most direct and integrative indicator of local, regional, or global biological condition. Biological assessments give us a way to evaluate whether our monetary valuations and ecological footprints are telling the truth about human impact on the biosphere. Biological assessments permit a new level of integration because living systems, including human cultures, register the accumulated effects of all forms of degradation caused by human actions.

Direct, comprehensive biological assessment has been done for many aquatic systems; measures are less developed for terrestrial systems. The index of biological integrity (IBI), for example, was developed in 1981 to assess the health of streams in the U.S. Midwest and has since helped scientists, resource managers, and citizen volunteers to understand, protect, and restore rivers worldwide. The index borrows a page from well-known composite indexes of economic performance—the concept of multiple indicators—and applies it to animals and plants in bodies of water. The specific measurements (Table IV) are sensitive to a broad range of human effects in waterways, such as sedimentation, nutrient enrichment, toxic chemicals, physical habitat destruction, and altered flows. The resulting index combines the responses to human actions of both biological parts (such as species) and processes (such as food web dynamics).

Indexes of biological integrity have been developed for a number of aquatic and terrestrial environments; the widest-used indexes for assessing rivers examine fishes and benthic (bottom-dwelling) invertebrates. These groups are abundant and easily sampled, and the species living in virtually any water body represent a diversity of anatomical, ecological, and behavioral adaptations. As humans alter watersheds and water bodies, shifts occur in taxonomic richness (biodiversity), species composition (which species are present), individual health, and feeding and reproductive relationships.

Sampling the inhabitants of a stream can tell us much about a stream and its landscape. Biological diversity is higher upstream of wastewater treatment plants than downstream, for example, at the same location, year-to-year variation is low (Fig. 1). Biological sampling also reveals differences between urban and rural streams. For instance, samples of invertebrates from one of the best streams in rural King County, Washington (United States) contain 27 kinds, or taxa, of invertebrates; similar samples from an urban stream in Seattle contain only 7. The rural stream has 18 taxa of mayflies, stoneflies, and caddisflies, the urban stream only 2 or 3. When these and other metrics are combined in an index based on invertebrates, the resulting benthic IBI (B-IBI) ranks the condition, or health, of a stream numerically (Table V). The B-IBI for the rural stream in King County was 46 (the 10-metric index maximum is 50); that for the urban stream, 12 (the index minimum is 10).

A benthic IBI can also be used to compare sites in different regions. Nearly pristine areas in Wyoming’s Grand Teton National Park have near-maximum B-IBIs. Streams with moderate recreation taking place in their

washes have B-IBIs that are not significantly lower than those with no human presence, but places where recreation is heavy are clearly damaged. Urban streams in the nearby town of Jackson are even more degraded, yet not as bad as urban streams in Seattle.

The core message embodied in biological assessment is that preventing harmful environmental impacts goes beyond narrow protection of clean water or clear skies, even beyond protecting single desired species. Certain species may be valuable for commerce or sport, but these species do not exist in isolation. We cannot predict which organisms are vital for the survival of commercial species or species we want for other reasons. Failing to protect phytoplankton, zooplankton, insects, higher plants, bacteria, or fungi ignores the key contributions of these groups to healthy biotic communities.

No matter how important a particular species is to humans, it cannot persist outside the biological context that sustains it. Direct biological assessment objectively measures this context.

VI. RECOGNIZING AND MANAGING ENVIRONMENTAL IMPACTS

Every animal is alert to dangers in its environment. A microscopic protozoan gliding through water responds to light, temperature, and chemicals in its path; it turns or retreats at the first sign of something noxious. A bird looking for food must decide when to pursue prey and when not, because pursuit might expose the bird to predators. The bird might risk pursuit when it is hungry but not when it has young to protect. Animals that assess risks properly and adjust their behavior are more likely to survive; in nature, flawed risk assessment often means death or the end of a genetic line.

Humans too are natural risk assessors. Each person chooses whether to smoke or drink, to drive a car or ride a motorcycle and at what speeds, to fly or take the train, to engage in "extreme" sports or go for a woodland stroll. Each decision is the result of a partially objective, partially subjective internal calculus that weighs benefits and risks against one another.

Risk is a combination of two factors: the numerical probability that an adverse event will occur and the consequences of the adverse event. People may not always have the right signals about these two components, however, and so base their risk calculus on the wrong clues. Urban dwellers in the United States generally feel that it is safer to drive home on a Saturday night than to fly in a jetliner, for example. Even though the numerical odds of an accident are much higher on the highway than in the air, people fear more the consequences of an airliner falling out of the sky.

Human society also strives to reduce its collective exposure to risks, primarily through government agencies responsible for protecting the public's interests. Governments do not hesitate to use military power and international agreements to protect their people from external aggression. They have, albeit more reluctantly, also used their regulatory power to reduce workplace risks and risks associated with consumer products like automobiles. But people and their governments have been much less successful in defining and reducing a broad range of ecological risks, largely because they have denied that the threats are real.

Society has long behaved as if its activities did not

* Benthic index of biological integrity: the highest possible score is 50, the lowest is 10.

* See Fig. 1 for graphs of selected B-IBI metrics at these sites.

Entail any risks to nonhuman living systems, that is, any ecological risks. The plans generated by economists, technologists, engineers, and even ecologists typically assume that the lost and damaged components of living systems are unimportant or can be repaired or replaced. Widespread ecological degradation has resulted directly from the failure of modern society to properly assess the ecological risks it faces. Like ancient Egypt's or Easter Island's fate, our civilization's future depends on our ability to recognize this deficiency and correct it.

Risk assessment as formally practiced by various government agencies began as a way to evaluate the effects on human health of toxic substances, usually the effects of single substances, such as pollutants or drugs, from single sources, such as a chemical plant. During the 1990s, the focus widened to encompass mixtures of substances and also ecological risks. Ecological risk assessment by the U.S. Environmental Protection Agency asks five questions: Is there a problem? What is the nature of the problem? What are the exposure and ecological effects? (A hazard to which no one or nothing is exposed is not considered to pose any risk.) How can we summarize and explain the problem to 'stakeholders' (both at-risk populations and those whose activities would be curtailed)? How can we manage the risks?

Even though these are good questions, ecological risk management has not made any visible headway in stemming biotic impoverishment. Its central failing comes from an inability to correctly answer the second question, What is the nature of the problem? Our present political, social, and economic systems simply do not give us the right clues about what is at risk. None of society's most familiar indicators—housing starts, gross national product, index of leading economic indicators, educational testing scores, air quality alerts, even number of threatened and endangered species—measure the consequences, or risks, of losing living systems.

Moreover, ecological risk assessment is still an assessment of the risks of business as usual, not an evaluation of potential benefits from alternatives to business as usual. When deciding what level of grazing to allow, for example, ecological risk assessors still examine the risks to, or impacts on, existing resources such as soil, water, and vegetation. They do not ask what the benefits of different grazing regimes would be; neither do they consider the benefits of no grazing at all, even though the no-grazing alternative might offer the greatest ecological, and ultimately societal, benefits.

If biotic impoverishment is the problem, then it makes more sense to direct environmental policy toward protecting the integrity of biotic systems. Aldo Leopold, in *A Sand County Almanac*, was the first to invoke the concept of integrity in an ecological sense: 'A thing is right when it tends to preserve the integrity, stability, and beauty of the biotic community. It is wrong when it tends to do otherwise.' Integrity implies a wholeness or unimpaired condition. In present biological usage, integrity refers to the condition at sites with little or no influence from human activity; the organisms there are the products of natural evolutionary and
biogeographic processes in the absence of humans. Ty-
ing the concept of integrity to an evolutionary frame-
work provides a benchmark against which to evaluate
sites that humans have altered.

Directing policy toward protecting biological integ-
ruity—as called for in the United States’ Clean Water Act,
Canada’s National Park Act, and water policy directives
being established by the European Union—does not,
however, mean that humans must cease all activity that
disrupts a pristine earthly biota. The demands of feed-
ing, clothing, and housing billions of people mean that
few places on Earth will maintain a biota with evolution-
ary and biogeographic integrity. Rather, measurements
founded on the evolutionary idea of integrity allow us
to directly assess biotic condition and to compare that
condition with what might be expected in a place with
little or no human influence. At least then we can make
an informed choice: continue with activities that de-
grade biotic condition or think of an alternative.

Ethical arguments aside, humans’ own dependence
on living systems makes it in our interest to manage
our activities so they do not compromise a place’s ability
to support those activities in the future; that ability can
be called ecological health. Ecological health describes
the preferred state of sites heavily used for human pur-
poses: croplands, tree farms, water bodies stocked for
fish, and urban areas. Integrity in an evolutionary sense
cannot be a goal at these places, but we should avoid
practices that so damage places that we cannot continue
to use them. Agricultural practices that leave soils
salted, lower regional water tables, and erode fertile
topsoil faster than it can be renewed destroy prospects
for future agriculture; such practices are unhealthy.

In contrast to risk assessment, and more akin to
ecological benefits assessment, striving to protect bio-
logical integrity is more likely to lead away from technolo-
gical fixes for environmental problems and toward
practices that prevent ecological degradation and en-
courage restoration. Biological integrity as a policy goal
turns our focus away from maximizing the goods and
services provided for the human economy and toward
ways to manage human affairs within the bounds set
by the natural economy. It begins to turn our attention
away from “How much stress can landscapes and eco-
systems absorb?” to “How can responsible human ac-
tions protect and restore ecosystems?” It could even
help avoid contentious fiscal allocation issues that arise
when massive emergency operations—like rescuing en-
dangered Pacific salmon in the Columbia River—are
needed to pull species back from the brink of extinction.

To be sure, managing for biological integrity requires
a deep commitment to self-imposed limits on human
population size, curbs on consumerism, less-selfish atti-
itudes toward land stewardship, and the realization that
the biosphere matters. Instead of calling on human
technical and spiritual井springs to manage resources,
we have to call on them for managing human affairs.
We have to find and use appropriate measurements for
all the factors contributing to biotic impoverishment,
be they climate change, overharvesting, agriculture, or
environmental injustice.

Managing our affairs to prevent ecological risks re-
quires integrating ecological systems and human social
and political systems. The ecological world is a com-
plex, variable system. We cannot predict with certainty
the intensity of the next El Niño drought or rainstorm.
We cannot know with assurance whether the cumula-
tive effects in a place will turn the next earthquake into
da disaster or an inconvenience. We cannot calculate
the absolute risks (or benefits) of pumping (or not
pumping) a given tonnage of carbon dioxide into the
air. Purely quantitative risk assessment only works in
the absence of such uncertainties.

Instead, when managing for ecological risks, people
and their governments need to expect the unexpected
and develop formal, yet flexible means of coping with
environmental surprises. Rather than plunge ahead
with projects entailing ecological risks because they can
be done, decision makers should follow the precaution-
ary principle, which holds that regulators should act
to prevent potential environmental harm even in the
absence of certainty. It acknowledges the existence of
uncertainty rather than denying it, and it includes
mechanisms to safeguard against potentially harmful
effects.

Though inappropriate ecological risk assessment and
management is more often the norm today, modern
institutions can recognize ecological threats correctly
and respond to them in time. The Montreal Protocol
is a prime example. Just over a decade after its adoption,
satellite measurements in the stratosphere indicated
that harmful chlorine pollution was in fact on the
decline.

VII. RECLAIMING LOST CONNECTIONS

Early in the 20th century, two sciences of “home main-
tenance” began to flourish: the young science of ecology
(from the Greek oikos, meaning home) and a maturing
neoclassical economics (also from oikos). Ecology arose
to document and understand the interactions between
organisms and their living and nonliving surroundings—in essence, how organisms make a living in the natural economy. In fact, Ernst Haeckel, who coined the term in the 1860s, defined ecology [in an 1870 article] as "the body of knowledge concerning the economy of nature." Neoclassical economics reinforced humans' self-appointed dominion over nature's free wealth and brought unparalleled gains in societal welfare in some places, but it also divorced the human economy from the natural one on which it stands.

Monitored by both those sciences, human actions and their effects have reached scales unprecedented in the history of life. We have altered the earth's physical and chemical environment, changed the planet's water and nutrient cycles, and shifted its climate. We have unleashed the greatest mass extinction in 65 million years and disrupted the human and human communities worldwide. In trying to make our own living, we have contributed not only to the global loss of individual lives and loss of species but, worse, to the loss of life itself—the removal of life from the biosphere. In the end, life—and earth's capacity to sustain life—is at risk.

Early in the 21st century, we need a new science and art of home maintenance, one that helps us understand and interpret the consequences of human-driven change. We need a new story, a different worldview, to guide our behavior, one that is in harmony with nature's economy. We must seek a balance between our modern industrial economies and our homelands' natural economies. As individuals and as societies, we need to understand the consequences for the present and future biosphere of what we do.

To reclaim our connections to the natural world, those of us insulated within industrial societies have to start small, with connections we can understand—like what plants and animals live in our backyards, which chemicals are used to grow our coffee, which laborers glued the soles on our walking shoes, where the pulp in our newspapers came from. We have to pay attention to how living systems respond to our behavior. In order to live, we have to let live. In his 1995 contribution to A New Century for Natural Resources Management, environmental ethicist Holmes Rolston Ill writes, "The next millennium is, some say, the epoch of the end of nature. But another hope is that we can launch a millennium of culture in harmony with nature."

GLOSSARY

biological diversity (biodiversity) The collection of genomes, species, and ecosystems occurring in a geographically defined region (NRC, 1995).
coastal zone Zone whose terrestrial boundary is defined by (a) the inland extent of astronomical tidal influence or (b) the inland limit of penetration of marine aerosols within the atmospheric boundary layer and including both salts and suspended liquids, whichever is greater; the seaward limit is defined by (a) the outer extent of the continental shelf (approximately 200 m depth) or (b) the limits of territorial waters, whichever is greater (Hayden et al., 1984).
estuary Semi-enclosed coastal body of water that has a free connection with the open sea and within which seawater is measurably diluted with freshwater derived from land drainage (Pritchard, 1967).

functional diversity Variety of different responses to environmental change, especially the diverse time and space scales with which organisms react to each other and to the environment (Steele, 1991).
metapopulation An abstraction of the population to a higher level at which individuals frequently move from one place (population) to another, typically across habitat types that are not suitable for their feeding and breeding activities, and often with substantial risk of failing to locate another suitable habitat patch in which to settle (Hanski and Gilpin, 1991).

ESTUARIES ARE AMONG THE MOST IMPORTANT INTERCONNECTIONS between land and sea. They are situated in the coastal zone, which accounts for a disproportionate amount of global ecological functions. For example, the coastal zone (modified from Pernetta and Milliman, 1995):

• occupies only 18% of the surface of the globe, 8% of the ocean surface, and 0.3% of ocean volume;
• but provides for up to 50% of global denitrification, 80% of global organic matter burial, 90% of global...
sedimentary mineralization, 75–90% of the global sink of suspended river load and its associated elements/pollutants, and in excess of 50% of present-day global carbonate deposition;

- also supplies approximately a quarter of global primary production, around 14% of global ocean production, and 90% of the world fish catch.

It follows that estuaries, as major pathways of aquatic exchange between land and sea, are major influences on a large proportion of these functions.

I. INTRODUCTION

Some of the steepest environmental gradients on planet Earth occur in the coastal zone, where land, sea, and atmosphere uniquely interact to exchange energy and materials. Also, the dynamic linkages among biological, physical, and chemical systems are exceptionally strong in estuaries, and are characterized by cyclic changes that occur at different frequencies—such as for tides, salinity cycles, freshwater inputs, light, and temperature stratification. Estuaries also bear the brunt of extreme events, such as flooding, storms, hurricanes, and seasonal sea ice. All of these are of importance for organisms, which have evolved suites of adaptive mechanisms to cope.

Estuaries have usually been considered as transitional areas between freshwater and saltwater environments. However, relatively few species are totally confined to estuarine conditions, even though various stages of many species’ life cycles are estuary-dependent. This raises questions about whether estuaries can be considered as transitional or as more-or-less autonomous ecosystems in their own right. The distribution of biodiversity provides important information toward the resolution of this apparent dichotomy, which needs to be clarified. These questions require both ultimate, historical-evolutionary explanations and proximate, functional-ecological explanations.

Despite the location of estuaries in the critical portion of Earth called the “coastal zone,” the Global Biodiversity Assessment (Heywood and Watson, 1995) contains no sections specifically devoted to them; the term “estuary” does not even appear in the index! Nevertheless, this volume does characterize biodiversity as comprising three disciplines, which also apply to estuaries:

1. taxonomy: provides the reference system and depicts the pattern or tree of diversity for all organisms;
2. genetics: gives a direct knowledge of the gene variations found within and between species; and
3. ecology: provides knowledge of the varied ecological systems in which taxonomic and genetic diversity are located, and it also provides the functional components.

Evolutionary biology brings these together, as it provides explanations of how biodiversity arose, and the processes, such as speciation and extinction, by which it continues to change.

The third aspect of biodiversity, namely, the functional-ecological aspect, is the focus of this article. In this respect, it is worthwhile to note that, even today, estuarine science continues to be organized along disciplinary lines. Although the study of land–seascape ecology of estuaries remains in its infancy, there are extensive publications on geomorphology, land–sea interactions, coastal zone management, and other disciplinary lines. Although the study of land–seascape ecology of estuaries remains in its infancy, there are extensive publications on geomorphology, land–sea interactions, coastal zone management, and other disciplinary lines. Although the study of land–seascape ecology of estuaries remains in its infancy, there are extensive publications on geomorphology, land–sea interactions, coastal zone management, and other disciplinary lines.

The distribution of estuaries corresponds to regional and coastal characteristics; that is, they tend to be extensive, large, and numerous where coastal plains are wide and flat, but are relatively small where coastal plains are steep and narrow. Particularly in the former, estuaries and associated lagoons constitute a much higher percentage of the coasts than is generally recognized. In fact, many of the world’s largest cities (London, New York, Karachi, Amsterdam, Alexandria, Tokyo, etc.) have been built on or near drained marshes or filled land adjacent to estuaries. In the United States, 80–90% of the Atlantic and Gulf Coasts and 10–20% of the
Estuaries are best understood in the context of the coastal zone, definitions of which vary. Ketchum (1972) was among the first to take a functional perspective, that the coastal zone "is the broad interface between land and water where production, consumption, and exchange processes occur at high rates of intensity." NERC (1992), on the other hand, defined the coastal zone as: "An indefinite zone of land and sea that straddles the shoreline; includes all land that is the product of, and/or at risk from (Holocene) marine processes, and extends seaward from the shoreline to water depths of about 30 m." The key element is "marine processes" and, from that point of view, it seems best to adopt Ketchum's broader view. Accordingly, Hayden and, from that perspective, it is most reasonable to assume that the communities of estuarine biota that exist today are as young and equally subject to change.

Many estuaries around the world have been studied in some detail. The North American bias in this article reflects the considerable body of research that has been conducted on North American estuaries during the past few decades, motivated unfortunately by the depleted, over-enriched, polluted, and over-populated states of many of them, some aspects of which will be examined in the Chesapeake Bay case study in Section V.

II. ESTUARINE CLASSIFICATION

Classification is essential as a comparative reference system, for otherwise data and information cannot be made comparable among estuaries. Various classifications, or typologies, of estuaries have been attempted, but these are mostly physical; no typology is directed specifically to biodiversity, even though the distributions of estuarine species have resulted in various classification schemes.

To my knowledge, the first classification was the so-called 'Venice system' (Anonymous, 1999), in which estuaries were divided into salinity zones. This was modified later by Bulger et al. (1993) on the basis of species' salinity tolerances. These two schemes align rather closely and may be compared as follows (Anonymous, 1999 = V; Bulger et al., 1993 = B; ppt = parts per thousand):

- Limnetic: freshwater, 0.5 ppt (V); freshwater, 4 ppt (B)
- Oligohaline: 0.5–5 ppt (V), 2–14 ppt (B)
- Mesohaline: 5–18 ppt (V), 11–18 ppt (B)
- Polyhaline: 18–30 ppt (V), 16–27 ppt (B)
- Euhaline: 30 ppt–full marine (V), 24–ppt marine (B)

The reason for the differences in salinity ranges between the Venice system and Bulger et al. is that the former was derived from salinity, whereas the latter was derived analytically from species' salinity tolerances, in which the zones would be expected to overlap. In both cases, however, the compartments are over-simplified, as estuaries exhibit many characteristics that influence biotic distribution and the distinction of estuarine zones, variably identified as "upper reaches," "upper-middle reaches," "lower reaches," and so forth. Nor do salinity-derived systems distinguish zones according to
variations in bottom type, water movement, volume of flow, and other attributes important to the biota. Another classification concerns basin geomorphology, which is of obvious importance for circulation patterns. Classification on this basis appears in many texts and may be summarized as:

- coastal plain estuary (drowned river valley): Usually confined to areas with a wide coastal plain where seawater has invaded existing rivers because of sea level rise since the Pleistocene Ice Age. Generally the up-estuary limit is where chlorinity is about 0.06% (salinity about 0.1%); above this point there may be a portion of tidal freshwater.
- fjord: Generally U-shaped in cross section, in which the sides are steep and have been glaciated. May be fed by a river, have a deep basin, and a shallow sill may be present near the mouth.
- bar-built: Occurs in flat, low-lying areas, where sand tends to be deposited in bars lying parallel to the coast. Usually shallow and wind-mixed. Can be a composite of drowned river valleys and embayments, and occurs when offshore sand barriers are built between headlands into a chain to enclose the body of water. May be fed by multiple rivers, but the total drainage area is usually not large.
- tectonic: A miscellaneous category including estuaries formed from faults or folding of Earth’s crust. Often have an excess of freshwater flow.

The interchange of freshwater and seawater provides yet another classification. The inlet (mouth) must be of sufficient dimension to allow mixing of seawater and freshwater, and the dilution of seawater provides the density gradients that drive characteristic circulation patterns. In terms of this interchange, the general classification is:

- salt wedge: Wherein a layer of relatively fresh water flows out at the surface.
- partially mixed (moderately stratified): Wherein tidal flow, turbulence, and mixing are increased, tending to erase the salt wedge.
- vertically homogeneous: Wherein tidal flow is strong, river runoff is weak, and all stratification is broken down.

Combinations of these typologies are possible; that is, it may be possible to find a stratified or a mixed bar-built estuary, or a fjord with a salt wedge or not. Furthermore, the extents of salinity zones can vary considerably for all categories. Such combinations of structure and hydrologic process result in highly varied conditions in the distributions of, for example, sediment, phytoplankton, submerged aquatic vegetation, and fishes and invertebrates. Additionally, variations in freshwater inputs, circulation, turbulence, and mixing can modify the typology.

A final classification concerns estuarine evolution, such as that of Roy (1984) for estuaries of New South Wales, Australia. There, estuaries are of three successional types: drowned river valleys, barrier estuaries, and saline coastal lakes. All are characterized by infilling during relatively short time spans. This affects their size, configuration, the invasion of mangroves and other aquatic vegetation, and fish communities. Biodiversity maxima are reached in the intermediate stages, because faunal population densities and species diversity increase with ecological complexity. However, as infilling becomes more advanced, the estuary becomes simplified and biological diversity declines. Therefore, estuarine geology, hydrology, and biology form a hierarchical succession.

### III. ESTUARINE BIODIVERSITY

From the foregoing discussion, the impression may be gained that estuaries are simply transitional and, therefore, not biologically diverse. Indeed, Sanders (1968) found that estuaries are relatively non-diverse biologically, but also noted: “What is significant is that each environment seems to have its own characteristic rate of species increment.” This is to say that salinity, for example, is an important determinant of the distribution of the biota, but also that estuaries exhibit high habitat and land–seascape diversity, a consequence of which is high variability among the biota and a high degree of biotic interaction. Thus, estuarine biotic communities would be expected to be especially varied and complex, contrary to earlier impressions of estuarine biological and ecological simplicity. Additionally, their biota have evolved resiliency to disturbance, both natural and human-caused. This is expressed at species, community, and ecosystem levels, leading to the impression that estuarine species are facilitative with respect to estuaries as preferred environments. These characteristics have resulted in a tendency to describe any species that enters estuaries, or those that tolerate brackish waters, as “estuarine,” which can be misleading. Nevertheless, some species seem to be restricted to estuarine and near-shore environments, at least at some life-history stage. A notable example concerns temperate oysters, which build extensive reefs in...
and the invertebrates—aquatic, xanthid mud crabs, improvisus, cea mamatorium, Rhizophora mangle, alterniflora, Zostera marina, Ruppia maritima, Cymodoceae. Carriker concentrated mainly on benthic invertebrates, but concluded that an “estuarine biocenose” may be justified as a discrete functional aggregation of interdependent, regularly recurring, dominant, benthic populations that are strongly represented numerically. He acknowledged that much needs to be learned of ecology and life histories to justify this, but that the estuarine biotope appears to be more than “just a simple overlapping of factors (an ecotone) extending from the sea and the land, but is characterized by a unique set of its own factors arising from within the estuary from the materials and forces contributed by its bounding environments” (Carriker, 1967).

Some of the dominant, or “true,” macroscopic biota of estuaries that he named are the plants—Sparganium alterniflorum, Zostera marina, Ruppia maritima, Cymodocea mamatorium, Rhizophora mangle, and Avicennia nitida, and the invertebrates—Nereis diversicolor, Balanus improvisus, xanthid mud crabs, Uca pugnax, Callinectes sapidus, Mya arenaria, Mytilus edulis, Modiolus demissus, and Crassostrea virginica. Additionally, he noted that characteristic estuarine habitats include tidal marshes, mangrove swamps, seagrasses, oyster reefs, soft clam–worm flats, and others. Finally, Carriker stated that: “Little is known of the sum of these effects on community structure, but they do emphasize the need to consider benthic organisms in the context of the total ecosystem rather than as an independent benthic biocenose.” This statement, made a third of a century ago, has yet to be fully realized.

Fishes are the best known of aquatic groups in a general sense, mostly due to their commercial value. Therefore, insights into “estuarine dependency” may be best revealed through their study. One reason for this is their mobility in which various life-history stages inhabit quite different environments. Winemiller (1995) reviewed fish ecology and made the following points. First, fishes are by far the most diverse vertebrates, and they inhabit an incredibly wide range of aquatic habitats from pole to pole. Second, fishes are ecologically diverse, with a wide variety of food habits, behaviors, reproductive habits, physiologies, and morphologies. Third, fishes exhibit a range of life-history strategies that result from trade-offs among various attributes, including clutch and egg size; these strategies can be classified as opportunistic, periodic, and equilibrium; but a range of intermediate strategies also exist. Finally, fishes and their diversity in ecosystems can be used as “indicators” of environmental conditions.

Recently, much attention has been directed toward the early life histories of fishes, as this is closely related to recruitment and, therefore, of much interest to fish ecologists and to fisheries. Houde (1997) provided a review of the selection factors that are of special importance in this regard. Able and Fahay (1998) extended studies on juvenile stages of fishes to “estuarine dependence” and determined that the numbers of permanent estuarine residents is relatively low, at least in part because estuaries exhibit extremes in environmental conditions. Also, the fish diversity of estuaries is augmented by transients, such as freshwater species that occasionally occur in estuaries and marine species that spawn at sea but whose young use estuaries as nurseries. Therefore, the estuarine fish fauna includes both residents and transients and a wide range of sizes, ages, and adaptations. In addition, those species that have successfully invaded estuaries usually inhabit only a small number of broad niches, implying that larger estuaries have larger numbers of species owing to increased habitat and niche complexity.

Able and Fahay found that, of the species for which good information is available, 60% are transients, 28% are residents (uncannily close to the “educated guess” of C. R. Robins and myself that 27% are “obligate” on estuaries; see Section V), 6% are infrequent, and 6% are unclassifiable. Furthermore, they have suggested the following adaptive groups for juveniles:

**Group I. Facilitative estuarine breeders**:
- Species whose nurseries are either in estuaries or on the inner shelf (e.g., *Menidia menidia, Menidia cantis*).

**Group II. Seasonal residents**:
- Species whose adults migrate into estuaries to spawn in spring or summer (e.g., *Centropristes striata, Brevoortia tyrannus*).

**Group III. Anadromous species**:
- Species whose adults migrate through estuaries in order to spawn in freshwater (e.g., *Morone saxatilis, Allosa spp.*).

**Groups IV–VI. Early users, delayed users, and distant spawners**:
- Species that spawn exclusively in the ocean, but the location, timing, and manner of use
of estuaries by young-of-the-year juveniles vary (e.g., Pollachius virens, Prionotus carolinus, Mugil cephalus).

Group VII. Expatriates: species whose estuarine larvae come from distant spawning (e.g., Chrysopteris ocellata, Monacanthus hispidus).

Group VIII. Summer spawners: the largest group, represented by shallow-water spawners whose larvae develop in the immediate vicinity of spawning sites (e.g., Cyprinodon variegatus, Fundulus heteroclitus).

Group IX. Winter–spring spawners: a few species that spawn in the winter or spring (e.g., Pseudopleuronectes americanus).

Group X. Migrating spawners: species that undergo spawning migrations within the estuary (e.g., Morone americana).

Group XI. Species difficult to classify: species for which some populations appear to be estuarine and other populations do not (e.g., Tautogolabrus adspersus).

Able and Fahay (1998) caution that, for fishes at least, “estuarine dependence” depends on the resolution of three areas of research: (1) the need to sample well-defined areas thoroughly for habitat evaluation; (2) assessment of the effects of habitat loss; and (3) more detail on temporal and spatial use of habitats where early stages are collected. In short, a coherent understanding of the life-history factors that control the early life histories of fishes remains to be accomplished. The same no doubt holds for invertebrates. For macroscopic plants, the situation is perhaps less uncertain, as their life histories are simpler and assessments are more easily accomplished.

In sum, most truly estuarine species are typically resistant to environmental variations due to the extreme conditions of estuaries, and/or take advantage of favorable situations; consequently, they do not appear to have strong habitat associations. This makes difficult the strict establishment of a definition of “estuarine dependency.” Also, the seaward boundary of an “estuary” is often blurred, so that the definition of “dependency” is hampered by lack of comparative, quantitative data from offshore habitats. The easiest distinctions are for those species for which at least one stage is shown to be physiologically or behaviorally obligate, but good natural history and experimental data are required for this. Therefore, the question “What is an estuarine species?” remains elusive. In addition, the oft-made contention that estuaries with similar habitats may support similar species assemblages seems reasonable, but may be misleading if assumptions of estuarine dependency are based on occurrence rather than in an adaptive-evolutionary sense.

IV. ECOLOGICAL FUNCTION OF BIODIVERSITY

In addition to genome, species, and ecosystem aspects of biodiversity, a fourth category must be considered, namely, “functional diversity” (Steele, 1991; see Glossary), which concerns ecological functions with respect to environmental maintenance and change. Ecological functions within the coastal zone and its estuaries are complex and variable, and they must be understood before we can interpret the composition and patterns of biodiversity. Holligan and Reiners (1992) listed a number of factors that underlie the biological diversity of the coastal zone and its estuaries, first for natural processes:

Exchanges of Materials  Riverine and atmospheric export and import, groundwater exchange, and ocean–land material transport operate at various levels, but are presently poorly understood. [Recent information on anadromous fishes is shedding light on organic-matter transport; e.g., Hesslein et al. (1991); Bilby et al. (1996); Garman and Macko (1998).]

Physico-chemical Properties  The coastal zone is a region of high energy exchange due to interactive oceanic and atmospheric forcing associated with topographical discontinuities, density gradients caused by freshwater inflows, and seasonal heat exchanges. Deltas, estuaries, and lagoons are the major sites for transformation and accumulation of organic matter and sediment, and all are highly variable spatially and temporally, so that their average conditions are not good indicators of net fluxes. Estuaries, in particular, are “sites of complex interactions, related to salinity gradients, phase transformation involving particle–water reactions, and to biological processes that cause biogeochemical transformations” (Holligan and Reiners, 1992).

Biological Properties  Favorable conditions of light and nutrients in the coastal zone maintain high rates of primary productivity that are several times greater than for the open ocean, and even greater than for certain coastal upwelling areas; some coastal systems, such as salt marshes, mangrove swamps, mudflats, beds of aquatic vegetation, and coral reefs, exhibit even
higher productivity. Some areas act as sources, others as sinks, and the nature of the coupling of primary productivity to the bottom or to open waters may determine community structure and function.

**Biogeochemical Processes** Organic matter is readily reoxidized in coastal waters, but some poorly drained areas may become anaerobic. This is especially apparent in the bottom water of estuaries in summer, when temperatures are high.

Many present-day human activities influence both ecological functions and biological diversity:

**Altered Delivery of Freshwater** Freshwater impoundment by damming has decreased total discharge into estuaries and coastal seas by about 15% since the 1950s, an amount equivalent to a change in sea level of ~0.7 mm/yr. Seasonal flows have also been altered; alteration in the residence time of water in estuaries may have far-reaching effects on chemical processes.

**Changes in the Transport and Fate of Suspended Matter** Coastal subsidence, sediment starvation and consolidation, and nutrient levels have all been altered by human interventions. Land clearing especially on steep slopes, has increased sedimentation.

**Chemical Modification** Nutrients, eutrophy, and blooms have become widespread and their frequency seems to be increasing. Contaminants that are of most concern include heavy metals, synthetic organic compounds, radionuclides, and hydrocarbons.

**Ecosystem Modification** This takes many forms, from physical change, to habitat loss, to depletion of resources. The worst-affected areas are those with high human population densities, such as Southeast Asia, and along temperate coasts that have significant sources of pollutants, such as the Baltic Sea.

Longer-term processes that influence biodiversity are the effects of climate change, especially in response to global warming, should that continue to occur:

**Natural Variations in Climate** Many climate-change studies describe possible variations in the altered distributions of biota. However, rather subtle changes in climatic conditions can induce large ecological changes that reflect the sensitive nature of marine food chains to climate and to climate-dependent factors such as nutrient levels and salinity. The direct effects of climate are difficult to distinguish from those incurred by humans.

**Temperature** The largest climate changes are expected in the higher latitudes. Thus, the poleward extension of climate-sensitive species is to be expected in case of global warming. Temperature changes can also affect behavior and physiology (e.g., reproduction, feeding and food availability, predation, migration), so that predictions are destined to be speculative.

**Wind** Wind strongly influences upwelling and stratification, thus affecting productivity through nutrient and light availability. According to most climate change scenarios, wind intensity is expected to increase.

**Extreme Events** Short time-scale events are also expected to increase with climate warming, and these may induce dramatic, long-term changes. A single storm lasting <5 days can result in sand transport equivalent to two-thirds of the total for an average year. Tsunamis have had the greatest effects recorded to date.

**Changes in Sea Level** Presently, sea level is rising faster than the rate during the late Holocene due to a combination of thermal expansion of seawater and melting of ice as the climate warms. Severe impacts of sea level rise on deltas and estuaries are already apparent, partly because they are low-lying, strongly perturbed by humans, and exhibit enhanced erosion and subsidence. Natural communities of plants and animals play a crucial role in determining the response of the coastal zone to changes in sea level.

This array of effects requires the development of research programs to address hypotheses that are relevant to the ecological function of estuarine biodiversity. Among many possibilities, the following seem essential (slightly modified from Solbrig, 1991):

- For species: no aspect of life history has any influence on extinction probability.
- For communities: keystone species are essential for maintaining species richness in communities under all environmental conditions.
- For ecosystems: removal or addition of functional or structural groups that produce changes in temporal or spatial configuration of landscape elements will have no significant effect on ecosystem properties over a range of time and space scales.

These hypotheses can be clarified by means of a case-
By-case examination (see the Chesapeake Bay case study). For example, some species seem very alike in their life histories. However, redundancy in species function may mean that diversity and function are somewhat independent of one another. Many species of benthis, infauna and epifauna are extremely abundant and ecologically important in estuaries. Many feed on sediments, and those with complete alimentary canals can consolodate organic residues into often long-lived, sculptured pellets. The question is: Many species have similar ecological requirements and, therefore, are species replaceable?

With respect to physical structure, Roy (1984) stated that the ecology of an estuary depends on the geological stage it has reached in its evolutionary progression, and that the rate and direction of natural change provide a yardstick to assess impacts induced by humans. However, as Roy emphasized, factors influencing estuary development include (1) inherited factors, mainly of a geological nature, that control the size and shape of the basin and the nature of the sediment supply, and (2) contemporary factors of a process nature (such as tides, river discharge, waves, etc.) that influence modes of sedimentation, hydrodynamics, and the biota. This prompts the question: To what extent are structure and biodiversity related?

Mann (1982) observed that, in general, estuaries are more productive than adjacent shelf systems, bringing up the question of nutrient flushing. That is, estuaries tend to act as nutrient traps. Many are enriched by pollution; the Hudson is a spectacular example of enrichment of a large shelf area well beyond its mouth. Within 600 km² of sea at the apex of the New York Bight, phytoplankton production amounted to about 310 g C/m²/day, compared with only 100 g C/m²/yr at the edge of the shelf. Mann and Lazier (1991) also noted that the dynamics of coastal waters, including estuaries, are made complex by: (1) shallowness, resulting in relatively mixed water that may extend to the bottom, and dead biological material that may accumulate to release nutrients that are carried rapidly to surface waters; (2) tidal currents that create turbulent mixing, which has especially marked effects on food particles, fertilization of planktonic eggs, and larval dispersal; and (3) barriers to convection imposed by coastlines, meaning that wind drives surface water away from the coast, and upwelling is the only way for it to be replaced, bringing nutrients to the surface. The question here is: To what extent are enrichment and/or pollution and circulation related to biodiversity?

Turning to larval transport, a variety of organisms have adapted to the seaward flow of low-salinity water and a compensatory landward flow of bottom water in estuaries. Organisms can make vertical migrations to maintain themselves in the estuary, or to enter or leave it seasonally. For example, estuarine larval transport and retention mechanisms are evident on two scales: circulation patterns on a large, regional scale and small-scale, local water motion. There is evidence that oyster larvae (Crassostrea virginica) rise into the water column to be carried upstream, and that this is cued by increasing salinity associated with increasing upstream flow; larval of the blue crab (Callinectes sapidus), on the other hand, occur in maximum numbers in surface waters at the mouth of Chesapeake Bay at night as the salinity falls on the ebb tide (Boicourt, 1982). From this and other evidence, it has been concluded that the crab larvae develop offshore, then reinvaed as megalopa larvae or juveniles. Fishes have also been shown to vary their depths, some rising into surface waters during flood to remain in the estuary, and others doing the opposite to be taken out to sea. Thus, many invertebrates and fishes utilize the two-layered estuarine structure for dispersal, and this may not be entirely passive, as has often been assumed. Despite some improved knowledge, Boicourt's conclusion is still pertinent, that the larval transport and retention problem 'stands at the state of the art in both physical and biological fields.' The question is: Does recruitment depend on return or retention (in the strict sense) as the operative process, and to what extent do larvae determine their own fates?

As another example of the importance of functional diversity, juveniles of the five species of Pacific salmons (Onchorhynchus spp.) vary in time spent in estuaries, but for all of them a high proportion of their prey tends to be detritus feeders (Healey, 1982). This means that the configuration of the estuary and the efficiency of entrainment of detrital matter are important for juvenile salmon habitat. Retention of detritus is enhanced by restricted exchange with the ocean and low bed-load transport. Marshes and submerged aquatic vegetation are efficient detritus traps, and these habitats also shelter salmon from predation. Thus, it may be hypothesized that the complex of intertidal marshes, tidal creeks and secondary river channels, lower intertidal and subtidal weed beds, and basin morphology all contribute to the carrying capacity of the estuary for young salmon, and that the appropriate configurations must be conserved if salmon production is to be maintained. The question here concerns how the complexity of the land–seascape enhances biodiversity, and how this may operate differently for closely related species.

From these examples, it is apparent that, insofar as ecosystem functioning is concerned, the addition or

domain of a given size is not a simple endeavor. However, the simple fact is that under many management regimes, autonomy may be incorrectly assumed.

V. A CASE STUDY: THE CHESAPEAKE BAY

Chesapeake Bay is one of Earth’s largest estuaries. Its origin is that of a drowned river valley. Thus is the case for many estuaries associated with coastal plains, wherein the dominant processes are sedimentary and erosional and whereby the bottom is largely soft sand and mud. Chesapeake Bay’s one major hard feature is that of the oyster reef, formed by the eastern Oyster, Crassostrea virginicus.

Many scientists have observed the drastic decline of oysters and of oyster reefs during the past hundred years and more, and the associated ecosystem effects. From a structural point of view, oyster reefs represent a unique and dominant biogenic structure of the Bay. Their distribution and ecological importance during the mid-1800s were analyzed by McCormick-Ray (1998). Their loss would be expected to have extensive repercussions on biological, hydrological, erosional, and sedimentary patterns and processes, all of which can have major influences on biological diversity. Indeed, history has borne out this conclusion. For example, a review by Rothschild et al. (1994) stated that “considerable concern is voiced regarding Chesapeake Bay water quality and the effects of disease on oysters” and that “the effects of a diminished oyster population abundance cer-
tainly must have changed the ‘ecology’ of Chesapeake Bay, and these effects must have become evident at the time of maximum stock decline (1884 to 1910).”

To understand the ecosystem effects of the oyster and oyster reefs better, one must begin at the regional scale, wherein the coastal zone is conceived as a nested hierarchical system (Ray et al., 1997). The regional scale is that of biogeographic and physiographic provinces. The mesoscale is represented by major regional subdivisions, such as watersheds, estuaries, coastal islands, lagoons, and coastal–ocean fronts that separate major marine regimes. The smallest scale is that of the inter-

tacting mosaics of land–seascapes, for example, wet-

lands, hard and soft bottoms, and water masses that are distinguished by salinity, temperature, and density. The oyster reef represents this latter scale.

This hierarchy is illustrated in Fig. 1, which indicates top-down “controls” and bottom-up “feedbacks” and which places estuaries in a central role. First, the bio-

geographic province (and/or “region”) is an area whose limits are defined by the relative homogeneity of the biota. For example, the traditionally accepted bound-

aries for the Virginian Province are Cape Cod, Massa-

chusetts, to Cape Hatteras, North Carolina. These capes are significant points of deflection for major ocean cur-

rents, principally the warm, north-flowing Gulf Stream and the cold, south-flowing Labrador Current. At these capes, dramatic changes in coastal characteristics, such as water temperatures and circulation patterns, occur and these physical features play major roles in de-

termining the ranges of the biota. One major feature of the Virginian Province is the presence of very large estuaries, such as the Chesapeake and Delaware Bays.

Species’ ranges respond to these large-scale attrib-

utes, as well as to species’ physiological and behavioral adaptations. Fishes are a case in point. Of the almost 1100 East Coast fish species, 536 species presently occur in the Virginian–Carolinian region (Ray, 1997; Ray et al., 1997). Estuary-dependent species are drawn from this species pool. As discussed earlier, “estuary-

dependent” has usually been interpreted very broadly. C. R. Robins and I re-examined this matter and con-

cluded that occurrence and even abundance of fishes in estuaries do not necessarily infer “dependence.” Rather, we determined that a species must be truly “obligate” in an evolutionary, adaptive sense for this definition to apply; that is, if estuaries were removed,
FIGURE 1 A hierarchical model of coastal zone relationships, showing top-down “controls” and bottom-up “feedbacks” of coastal zone interactions, involving levels from biogeographic provinces, to estuaries, to the oyster reef. The biogeographic province provides the species pool from which estuaries may draw “estuary-dependent” representatives. This biota is influenced by the morphometrics of individual estuaries, leading to different species communities among the estuaries in a biogeographic region. The oyster is a “keystone” species both biologically and ecologically, as the reefs it builds influence the morphometrics of the estuaries in which it occurs. Over-harvesting of oysters in the Chesapeake Bay, and elsewhere, has had major effects on estuarine function, structure, and probably biodiversity as well. (From Ray et al., 1997.)

“dependent” species would be at risk of significant depletion, even to the point of local or regional extirpation. According to this definition, we determined that 151 species (27% of 556 species) qualify as “estuary dependent,” less than has been assumed in the past, but still a significant part of the total. This figure is remarkably consistent with the results of Able and Fahay (1998: see Section III). A principal components analysis of the ranges of these species resulted in four assemblages. Figure 2 shows these assemblages and demonstrates that so-called “faunal breaks” between provinces must be viewed as gradients, and not as “boundaries” in a rigid sense.

FIGURE 2 A principal components analysis of the ranges of 151 Carolinian and Virginian estuary-dependent species revealed the following assemblages: Component I = Virginian, Component II = Carolinian, Component III = tropical, and Component IV = boreal. These four assemblages overlap, as would be expected. (From Ray et al., 1997.)
This finding brings up the following question: How might changes in estuaries, human-caused or not, influence the composition of these fish assemblages? For insight into an answer, we must examine the dynamics of estuaries themselves. Many factors interact to characterize an estuary. Among these are drainage area, tides and mixing, estuary area, depth, dimension, water column stratification, floods, habitat types, and many others. A principal components analysis (Ray et al., 1997) revealed five components that may influence biological diversity: estuarine dimensions, dominance of marine processes, co-dominance of marine and freshwater processes, fjord-like attributes, and surface area. The interplay of these factors may be used to classify estuaries into the following types: (1) those that are long and wide with extensive catchment areas; (2) large, embayed, well-stratified estuaries with extensive seawater zones; (3) marine-dominated, deep, and well-stratified estuaries; (4) long and narrow, fjord-like estuaries, with large tidal prisms; and (5) estuaries with large surface areas. Chesapeake Bay falls somewhere between the first and second categories.

It seems reasonable, from what we know of the natural histories of the biota, that these estuarine types would be expected to host different communities of species, and further that different disturbance regimes would be expected to affect these estuarine types and their species’ communities differently. The conclusion seems obvious that biotic communities will differ among estuaries and that seasonal or weather-related changes in salinity and other factors will be reflected in the variability of biotic patterns. Furthermore, because the great majority of estuarine fishes, in particular, also occur over the continental shelf, fluctuations of estuarine fish communities would also be reflected, up-scale, by shelf-fish communities.

This approach offers a series of environmental top-down “controls” over biodiversity and ecosystem function. But this can not totally explain what might be the consequence of bottom-up environmental alterations. That is, the prediction of biodiversity and faunal dynamics requires that the response of the organism to the environment at different scales and the modifications the organism may make to the environment both be made explicit. For example, Fig. 1 indicates that the decline or removal of a species or a local structure, in this case oyster reefs, will influence the total biological diversity of the system by influencing environmental conditions through environmental feedbacks.

For the Chesapeake Bay, and many other Virginian–Carolinian estuaries, oysters are especially critical because they form reefs, which influence biodiversity at many levels (McCormick-Ray, 1998). The location of these reefs is not accidental. Their formation depends on the geometry of the estuarine basin, tidal stream channels and meanders, and other factors. Furthermore, oyster reefs influence estuarine development, sedimentation, and water clarity, and thus the formation of habitats (e.g., submerged aquatic vegetation, marshes, soft bottoms, and hard bottoms) for a host of organisms. In sum, the eastern oyster appears to be a classic example of a “keystone” species at the level of the ecosystem. Structurally and functionally, individual oysters and the reefs they build strongly influence species diversity and productivity. Additionally, the distribution of oyster reefs may be of fundamental importance to development of the estuarine land–seascape.

Another type of feedback concerns the fact that most species exist as a number of separate populations that mix together as one or more “metapopulations.” For example, an estuary-dependent species, such as menhaden (Brevoortia tyrannus), forms populations in individual estuaries, and these populations assemble over the shelf to form one or more metapopulations. Furthermore, these metapopulations join those of other species and become part of the shelf “metacommunity,” as illustrated in Figure 3. It follows that fluctuations of any one metapopulation within any one estuary will affect the total “metacommunity” to a greater or lesser extent (Ray, 1997). This form of biodiversity concerns community composition, not necessarily the presence or absence of individual species, and is strongly affected by functional alterations of estuaries. The conclusion is that at the scale of the large, regional ecosystem, each estuary may be conceived in terms of the sum total of individual oysters and the reefs they build strongly influence species diversity and productivity. Additionally, the distribution of oyster reefs may be of fundamental importance to development of the estuarine land–seascape.

The concepts presented in the case of the Chesapeake Bay suggest controls and feedbacks among organisms and the environment at several scales, in which one fundamental factor seems clear. East Coast estuaries have been perturbed in many ways, but one of the most dramatic for the Chesapeake Bay has been the depletion of oyster reefs and the practical eradication of their functional ecosystem role. Although data are lacking that would explain beyond doubt what changes have been perpetrated by the oyster’s decline in Chesapeake Bay, it seems apparent that, at the very least, the oyster reef’s demise has had a marked effect on the distributions of estuarine species, not necessarily because the
FIGURE 3 The concept of estuarine metapopulations and shelf meta-communities. Oyster reef metapopulations influence estuarine morphometrics and biodiversity. Consequently, the fish biota of various estuaries influence the fish metacommunity of the shelf.

reef is required habitat, but because of its functional importance to the Bay as a whole. It is possible that these effects may have cascaded up-scale to the adjacent continental shelf.

VI. FUTURE CHALLENGES

I make three points in conclusion. The first concerns the need for greatly increased attention to the natural histories of estuarine and shelf species. The natural histories of these organisms underlie both theory and management practice. The minimal requirements for informed conservation and management are descriptions of species’ life histories in the context of their environmental relationships.

Second, many estuarine organisms range widely and form metapopulations over the shelf, as components of estuary–shelf communities. Thus, the minimal scale for sustainability of biodiversity becomes that of the biogeographic region. Quantitative, landscape-level descriptions of the regional coastal zone, including estuarine habitats, are a necessary prerequisite for conservation and management.

Third, it has become a truism in ecology that no one scale adequately describes ecosystem phenomena. Rather, the interaction among phenomena on different scales must become the centerpiece of research and management. This strongly suggests that explanations for fluctuations in biodiversity, including those within biotic communities and at regional scales, will continue to be obscure until multiscale ecosystem functions are better understood. Ecosystem management is the logical outcome of interdisciplinary, multiscale knowledge. This recognizes that understanding the ecology and diversity of coastal zone biota depends in large part on understanding land–sea and estuarine interactions, and also on the joint application of metapopulation and land–seascape theory and methods.

The National Research Council (NRC, 1995) stated that a major future research objective is “to understand the patterns, processes and consequences of changing marine biological diversity by focusing on critical environmental issues and their threshold effects, and to address these effects at spatial scales from local to regional.” This objective cannot be met absent a specific consideration of estuaries as major, scale-dependent pathways of biotic and abiotic interchanges. Estuarine biodiversity, structure, and function have been severely modified by humans around the globe. Nevertheless, many estuaries remain either good candidates for restoration or relatively rich, productive, and resilient. Documentation of impacts is severely hampered by lack of long-term baseline information, inadequate assessment of biodiversity, lack of trained taxonomists, and difficulty in sampling.

Nevertheless, an extensive estuarine literature is now available, and it illustrates that control of pollution, development, excessive natural resource extractions, and changes in ecosystem function urgently need to be addressed. Problems may not be eliminated, only ameliorated, but increased understanding is essential for the future sustainability of estuaries. Carricker (1967) put the matter boldly three decades ago: “There is consequently an urgency to study estuaries before unenlightened defacement obliterates them and before it becomes expedient to investigate them primarily as outdoor pollution laboratories.”

I. Conservationists’ Ethical Consensus

There is widespread disagreement in modern societies regarding the proper human relationship to the rest of the natural world. Conservationists and conservation biologists, however, mostly agree on the following ethical principles: the diversity of organisms is good; ecological complexity and natural evolution are good; the untimely extinction of populations, species and biological communities is bad; biological diversity has great value both to people and in its own right; and human beings have both strong altruistic and strong self-interested reasons for preserving biodiversity.
Conservationists justify these principles in very different ways. One may value biodiversity because it is God's creation and testifies to God's glory; another because it is the natural culmination of evolution and global forces that have occurred over hundreds of millions of years; a third because of its value to science, perhaps humanity's noblest pursuit; a fourth because of its beauty and the enjoyment that current and future generations may take in it; a fifth because of its intrinsic value grounds a strong duty to protect it, regardless of human interests; a sixth because preserving biodiversity helps preserve human life-support systems. Such justifications may be more or less anthropocentric—centered on human interests. However different their ultimate justifications, conservationists tend to accept these ethical principles and work with others to preserve biodiversity.

Difficult ethical and practical issues emerge when we ask two further kinds of questions. First, what do these general principles entail? Given a high valuation of nature and a sense of personal responsibility to help protect it, what exactly is required of us as scientists and citizens? Second, how does our concern to protect biodiversity mesh with our obligations to humans? What if they clash? Such questions come up in numerous practical contexts and must be answered, although we cannot wait for certainty or full consensus in order to act.

II. CONSERVATION GOALS: HEALTH, INTEGRITY, SUSTAINABILITY

For much of the twentieth century, public and private land management goals have been primarily economic. It has become increasingly clear, however, that an exclusive focus on economic productivity leads to environmental degradation: pollution, the extinction of species, and the creation of a progressively simplified landscape. In response, laws have been passed directing government land managers to preserve the health and integrity of ecosystems. A focus on short-term economic returns also tends to undermine the long-term economic productivity of biological systems, such as forests and fisheries. Recognizing this, governments have begun to promote sustainability as an ideal in the use of natural resources. Conservationists hope that health, integrity, and sustainability specify goals concrete enough to guide us in our actions while commending themselves as basic values that a wide variety of people will share.

A. Health

Responding to widespread criticism of forestry practices, Canada's Provincial Forest Ministers agreed in 1992 that "our goal is to maintain and enhance the long-term health of our forest ecosystems, for the benefit of all living things both nationally and globally" (Westra and Lemons, 1993). Government agencies around the world have similarly embraced the notion of land health. Participants in a major symposium on ecological health defined it as follows:

An ecological system is healthy and free from "distress syndrome" if it is stable and sustainable—that is, if it is active and maintains its organization and autonomy over time and is resilient to stress. (Costanza et al., 1992)

Just as a healthy human being is free from disease and able to perform his or her characteristic functions well, a healthy forest or stream is free from air or water pollution, siltation, or invasions of exotic organisms. Such "stresses" impede or radically alter the systems' natural functions (such as photosynthesis or net primary productivity) and structure (often eliminating sensitive species and simplifying biological communities)(Table I).

Healthy ecosystems provide both natural biodiversity and a wide array of products and services valued by humans. For this reason, economic productivity (as measured in board feet, fish caught, or crops yielded) can sometimes stand as one measure of overall ecosystem health. Rapidly declining fish catches in Lake Victoria, due to the introduction of the Nile perch, signaled a decrease in the system's health. However, economic productivity may sometimes be increased by a radical simplification of an ecosystem, as when diverse, natural forests are converted to single-species, even-aged pine plantations, or when natural prairies are converted to cattle ranches (Fig. 1). Such simplified ecosystems are not necessarily economically productive in the long run, but if they are, then whether they are seen as unhealthy depends on whether preservation of native biodiversity is part of our definition of land health.

If simplified ecosystems are managed well, they may stay healthy for humans and a reduced biota, remain stable and resilient to stress, not pollute surrounding ecosystems (e.g., not dump excessive silt or fertilizer in streams), and continue to perform valuable ecosystem services. Because some relatively intensive land use is necessary for human survival and this can be done better or worse, it makes sense to apply concepts of

Note: Signs (+ or −) indicate direction of change compared with normal functioning of relatively unstressed systems. An asterisk indicates that a characteristic response was not sufficiently determined. Rapport et al. (1985).

land health to simplified ecosystems. At the same time, we must recognize that preserving as much biodiversity as possible in managed systems (croplands, lakes, forests) is desirable and that excessive simplification across a large landscape leads to extinction of species and loss of characteristic natural communities. Ecosystem health must be supplemented with the ideal of ecosystem integrity—at least in some areas (see the next section).

We should also remember an important difference between human health and ecosystem health. Individual human beings grow old, decay, and die, and while we fight this we also accept it. In contrast, we want healthy ecosystems in perpetuity, for their own good and the good of our descendants. Thus ecosystem health must also be supplemented with the ideal of ecological sustainability (see Section II,C).

B. Integrity

Amendments to the U.S. Clean Water Act of 1972 first set ecological integrity as a management goal by calling for the restoration and maintenance of "the chemical, physical, and biological integrity of the nation's waters" (Costanza et al., 1992). Rolston (1994) noted that "both integrity and health are combined fact-value words. Both convey the idea of wholeness and of unbroken functioning." But ecosystem integrity implies a greater measure of freedom from past and current human manipulation and a closer approximation to natural structure and functioning than does ecosystem health. Karr and Dudley (1981) defined ecological integrity as "the capability of supporting and maintaining a balanced, integrated, adaptive community of organisms having a species composition, diversity, and functional organization comparable to that of natural habitats of the region."

Integrity is a key environmental ideal because it encompasses the full preservation of biological diversity, including individual organisms, species, natural communities, and the ecosystem processes that have created and sustained them. It has taken a long time for this ideal to be acknowledged, even in supposedly fully preserved areas. For example, wolves, mountain lions, and other predators were routinely shot, trapped, and poisoned in U.S. national parks up until the 1960s. It is only in the last ten years that wolves, once extirpated, have been reintroduced into Yellowstone National Park. For most of this century, fires were suppressed throughout the national parks; they were perceived as dangerous to both people and forests. Over time, however, fire ecologists documented the historical role of fires in creating the landscape and preserving fire-dependent species of plants and animals. In response, land managers have introduced controlled burning into parks and allowed some lightning-ignited fires to burn. Improved ecological understanding and an attempt to distinguish between what is good for the ecosystem and what is
comfortable or familiar for people have shown that wolves and fire belong in the parks.

The fact that ecosystems are not as strongly integrated, clearly bounded, or stable as individual organisms complicates attempts to specify ecological integrity in particular cases. It is sometimes difficult to stipulate which outside influences represent assaults on integrity rather than mere changes. Recent study suggests that many ecosystems are relatively loose assemblages of species; that these assemblages may be relatively recent and transient creations; and that even left to themselves many natural communities will not necessarily reach a
particular, invariant climatic state but may instead reach any one of a number of more or less stable states, or no stable state whatsoever. If species assemblages are always changing naturally, why distinguish species that are extraported or introduced by humans, as when conservationists reintroduce wolves in the Rockies or eradicate wild boars in the Great Smoky Mountains? If there is no one natural end point to succession, why assume that human-created early-successional stages (fields of shrubs after clear-cuts) have less integrity than naturally occurring late-successional stages (old-growth forests)?

Still, ecosystems typically go through characteristic successional stages and support characteristic (if not invariant or exact) species assemblages. Though natural species assemblages change, this usually occurs on a time-scale that allows for much stability, the development of detailed interactions between organisms, and the increase of biological diversity at the landscape level. In contrast, human-induced changes typically decrease biodiversity and always lead to a landscape that is partly our creation. This loss of independence arguably marks a qualitative change in an ecosystem’s natural history and a corresponding loss of ecosystem integrity. Applying this complex concept to particular ecosystems thus involves attention to scale, knowledge of an ecosystem’s particular history, and comparison with the structures and functioning of similar ecosystems. Maximizing ecological integrity involves balancing the sometimes conflicting goals of freedom from human interference and preservation of historical natural communities.

Despite these complications, the desire to restore degraded ecosystems demands robust conceptions of ecosystem integrity and health. Ecologists attempting to restore degraded pasture-lands to native prairie in Wisconsin, worked-out strip mines to forests in Appalachia, or drained lands back to wetlands in Florida must set specific objectives (Fig. 2). As with land managers seeking to limit their effects on relatively pristine areas, restorationists have taken health and integrity, defined in relation to natural baselines, as goals for restored landscapes.

C. Sustainability

“Live Sustainably!” has become a rallying cry in the environmental movement. Like health and integrity, sustainability is a term that blends facts and values, helping us carry out our environmental convictions. At a minimum, sustainability involves preserving resources for future generations. But this minimum will not satisfy conservation biologists, who insist that part of what must be sustained is the full complement of biological diversity, for its own sake and for the benefit of humans.

Wide differences exist here. For instance, in 1987 the United Nations World Commission on Environment and Development (the Brundtland Commission) defined sustainable development as “development that meets the needs of the present without compromising the ability of future generations to meet their own needs.” The focus here is wholly on human beings. In this definition the mass extinction of species is sustainable, provided future generations of people can meet their self-defined needs. R. Noss summarized the shortcomings of such narrow, anthropocentric accounts of sustainability as follows:

A failure of those who promote sustainability to consider environmental and social limits to growth, an unwillingness to address the unsustainability of the current human population, much less its expected growth; a reluctance to confront the implications of the lifestyles of average citizens of the more affluent societies . . . a failure to recognize the claims of other species to their share of the planet’s resources. (Westra and Lemons, 1995)

Contrast the Brundtland definition with Barbier’s more generous definition of sustainable development: “to maximise simultaneously the biological system goals (generic diversity, resilience, biological productivity), economic system goals (satisfaction of basic needs, enhancement of equity, increasing useful goods and services), and social system goals (cultural diversity, institutional sustainability, social justice, participation)” (Munda, 1997). Such a definition implies a different conception of human development and a more restrained treatment of the non-human world than has prevailed up to this point in human history. Satisfying the basic needs of all people and creating just and flourishing societies are part of this goal; limitless wealth creation and unbounded consumerism are not.

Conservationists are particularly concerned to keep the definition of sustainability based in ethics and biology and not solely in traditional economics. Economical based definitions often define sustainability in terms of indefinite economic growth, but in the crowded, fossil-fuel-propelled world of the twenty-first century, continued emphasis on economic growth will inevitably undermine ecosystem health and integrity worldwide. We cannot sustain increased consumption
III. MANAGEMENT AND NONMANAGEMENT

Setting aside parks or wilderness areas where human beings are not permitted to use resources has been conservationists’ most effective tool in conserving biological diversity. Here the results from conservation biology are clear. Wild areas preserve greater numbers of native species than do areas managed for agriculture or forestry. Large protected areas are more likely than smaller ones to preserve full complements of native species. Some species need large areas of habitat to preserve minimum viable populations. Some species tolerate little human disturbance. Larger areas are less likely to suffer “edge effects” that render otherwise good habitat unusable by certain species.

A dilemma arises, however, because in order to preserve certain wild species or communities, we may have to actively manage wild or semi-wild areas. Rare, threatened plant populations may have to be fenced off from
ETHICAL ISSUES IN BIODIVERSITY PROTECTION

high populations of browsers or new populations created from seeds or cuttings. Small, widely scattered populations of an endangered mammal may have to be gathered together to preserve genetic variety or create viable populations. Controlled burning may have to be carefully introduced into a forest or field to preserve fire-dependent species (Fig. 3).

Most conservationists accept reintroductions of indigenous species into wild areas and other manipulations that have as their goal the preservation or re-creation of indigenous flora and fauna. But they sharply distinguish actions that have this goal from actions that support further resource extraction or tourist comfort (road building, tree harvesting, construction of lodges and restaurants), which they continue to oppose in wild areas. Further, they see value in the absence of manipulation itself and tend to view the need for heroic measures in pristine areas as an indication of what has already been lost.

As a practical matter, hands-on management will often be necessary to preserve biodiversity. Even our largest natural areas are increasingly "islands" of diversity surrounded by development. These islands will likely lose species over time, as predicted by conservation biology theory and confirmed by empirical study; more native biodiversity may be preserved by augmenting populations and managing habitat. Other semi-wild areas will continue to be utilized by humans; these areas support wild species that may also need management in order to survive. Some manipulation will be needed, in perpetuity, if we are going to preserve as much biodiversity as possible.

It should be noted, however, that heroic measures and intrusive management often fail to preserve species. Skeptics also warn that a casual acceptance of manipulation may lead to a loss of biodiversity, if all sorts of human purposes are allowed to vie with nature preservation on our park and forest lands. Too often, management of nature becomes a substitute for management of ourselves. Rather than close popular trails or campgrounds in Yellowstone National Park, for example, state officials sanctioned the culling of hundreds of deer in the Quabbin Preserve in central Massachusetts to prevent overpopulation, overdevelopment, and overconsumption that make such biodiversity management necessary. By managing ourselves more wisely, we can limit the need to manage wild nature.

IV. BIODIVERSITY PROTECTION AND ANIMAL RIGHTS

Conservationists typically argue that preserving species and whole biological communities should take precedence over preserving individual animals. In practice, this means that exotic animals may be sacrificed when necessary to preserve native species or overpopulous native or exotic animals may be sacrificed to preserve land health. These positions have provoked arguments with animal rights advocates, who might seem to be conservationists' natural allies.

For example, U.S. government agencies judged the continued existence of the endangered plant Santa Barbara live-forever (Dudleya traskiae) to be more valuable than the common rabbits that had been introduced on its island home. The rabbits, which fed on the plant's fleshy leaves, were killed to stop the destruction of this fragile plant species. In another example, state officials sanctioned the culling of hundreds of deer in the Quabbin Preserve in central Massachusetts to prevent overbrowsing as a way to allow tree regeneration and protect water quality. Protection of the overall health of the forest and continuation of basic ecosystem functioning (forest regeneration, water purification) outweighed the interests of individual deer.
FIGURE 3 Conservation management: intervention versus leave-it-alone. (B) This old-growth stand in the Olympic National Forest in Washington is the result of many years of keeping human disturbance to an absolute minimum. (Photograph by Thomas Kitchin/Tom Stack & Associates.)
Such practices seem mere common sense to many conservationists, but many animal rights advocates argue that they are misguided, for two reasons. First, animals (at least some higher animals) have rights or interests based on their consciousness or sentience (their ability to feel pleasure or pain). This means that we cannot sacrifice them casually for other goals, such as a healthy forest. Second, species and forests do not have rights or interests, because these complex aggregates are too loosely organized (see earlier discussion). To sacrifice the real interests of a higher animal to the bogus interests of a species or biological community is thus ethically mistaken.

Conservationists answer that as we learn more about biodiversity, we realize that its greatest value lies not in individuals but in the wholes that those individuals help constitute. It is the species that persists and evolves rather than the individuals, which come and go. It is the natural community that sustains and generates new forms of life. While an ethic based on individual rights best specifies appropriate human interactions, a less individualistic ethic is needed to properly value the natural world.

This ethical shift seems to be necessary for effective conservation. However, animal rights advocates have given strong arguments for respecting individual higher animals such as dogs, cats, rabbits, and wild horses. Conservationists, who usually value species over individuals, may concede that individual animals should not be sacrificed casually, but only if it truly is necessary to preserve species or the health of biological communities. They might add that individual animals should always be culled humanely, that is, with a minimum of suffering. This would rule out most trapping and much sport hunting, although these activities are routinely defended on conservation grounds.

For example, Quabbin Preserve managers might carefully monitor deer populations and tree regeneration and authorize hunting where appropriate. All deer kills would have to be performed humanely, and in some years no hunts may be authorized. Whereas a traditional wildlife management position would authorize hunting game birds and trapping beavers, mink, and muskrats as long as this was done sustainably, a position responsive to animal welfare might not allow any of these activities, unless they could be justified with reference to the good of the forest or particular species.

Conservation and animal rights ethics both typically lead beyond anthropocentrism—the belief that only human interests matter—and they are usually complementary. For example, a concern for individual animals leads logically to vegetarianism, which prevents much animal suffering and bloodshed. But since ‘eating lower on the food chain’ is less energy and land-use intensive, it also helps conserve resources and preserve biodiversity. Limiting consumption and distinguishing between needs, comforts, and luxuries are precisely what are needed to carry out both ethics. Nothing prevents individuals from living highly consistent lives that incorporate both ideals. We may act to limit animal suffering and preserve wild nature so that the entire realm of biodiversity can flourish.

V. BIODIVERSITY PROTECTION AND HUMAN RIGHTS

Conservationists often argue that individual organisms, species, and biological communities have intrinsic value—that is, value in addition to their usefulness to human beings—that obliges us to preserve them. This means human interests should sometimes be sacrificed to preserve biodiversity. For example, a developer should not build a housing project that destroys critical habitat for an endangered songbird species—whether or not it is legal to do so. The continued existence of this species is more important than the developer’s profits. His less-than-vital interests should be foregone or pursued in ways that do not sacrifice something infinitely more valuable: a natural species. In many cases, however, preserving biodiversity and furthering human interests are complementary goals, especially if we take a broad view of human interests. Present and future generations have strong material, aesthetic, scientific, recreational, and spiritual interests in preserving biodiversity.

A. Owls and People

The coniferous forests of the U.S. Pacific Northwest are some of the most majestic on earth, with thousand-year-old trees towering over crystal clear streams filled with salmon. As commercial timber harvesting escalated after World War II, the big trees fell and species dependent on old-growth forests such as the northern spotted owl (Strix occidentalis caurina) (Fig. 4), the marbled murrelet (Brachyramphus marmoratus), and various salmon species (Oncorhynchus spp.) declined dramatically. In response, environmentalists staged logging blockades and tree sittings during the 1980s and suc-
Figure 4. (A) The northern spotted owl is an indicator species for old-growth forests of the Pacific Northwest, a habitat coveted for its rich timber stands. (B) Demonstrators protest government and corporate policies that destroy forests and threaten species extinctions.
The political battle was often billed as “owls versus people,” but such a simplistic formulation was misleading. Reduced harvests resulted in the loss of thousands of logging jobs, but some reduction was inevitable, given unsustainably high harvest levels based on a one-time cutting of thousand-year-old trees. Logging restrictions helped preserve and create jobs in fishing and tourism and enhanced watershed maintenance, flood control, and other objectives. A calculation based on the full spectrum of long-term human interests would likely have resulted in substantially decreased timber harvesting. Still, old-growth forests do have great economic value as timber, and preserving more in reserves rather than cutting the big trees and moving to high-yield forest plantations may indeed lead to lower profits for industry and fewer overall jobs.

Are such trade-offs ever justifiable to prevent the extinction of species or important biological communities? Forestry industry executives and loggers’ unions said no. The interests of a logger in supporting his family should supersede the interests of animals or trees. Logging restrictions to protect other species are wrong because they lead to real human hardship for loggers and their communities. Environmentalists insisted that more logging jobs and higher corporate profits did not outweigh the permanent loss of species and the old-growth temperate rainforest itself. They also noted that industry and government had made no efforts to preserve logging and mill jobs when technological changes, log exports, or overharvesting had led to job loss in the past (see Fig. 4).

These considerations suggest a solution to the dilemma: harness the economic system to maximize both human interests and biodiversity protection. Whether we focus on intrinsic or instrumental value, the human communities of the Pacific Northwest have an interest in preserving their remaining old-growth forests. Fortunately, the regional economy generates enough wealth to provide laid-off workers with guaranteed health care, generous severance pay, and job retraining for those who want it. The big trees could be preserved and displaced workers supported by their fellow citizens. Such a course would not reconcile all conflicting interests or solve all problems: economic “winners” would have to be taxed to support economic “losers,” some loggers would have to give up a valued livelihood, and some businesses would have to forego profits or even fold. But many of the costs of environmental protection would be borne by society as a whole, which benefits from the preservation of biodiversity.

### B. Property Rights

When environmentalists won suits to limit logging in the Pacific Northwest, the resulting bans affected both private and public lands. To some observers, the restrictions on private lands were unjustified. In their view, the right to own and control property is essential. Dictating to individuals or corporations what they can or cannot do on their own land is seen as an intolerable abridgment of that freedom. In devising a plan to continue tree harvesting in the region, the U.S. government focused preservation efforts on public lands, allowing maximum freedom to private landowners. Does private property ownership give owners unlimited control over their land, even if their actions contribute to the extinction of a rare or endangered species? Historically it often has, but morally it does not. Both the intrinsic value of species and duties to our fellow citizens to preserve a common biological heritage argue against such actions, regardless of how much profit must be foregone. Land ownership confers both rights and responsibilities.

What then of a small landowner who needs to cut an old-growth stand in order to send a child to college or keep the land in the family? Clearly as the need becomes greater, the ethical justification increases, even if some loss of biodiversity occurs. Hopefully, though, this small owner is not so poor that he must view his land solely as a money-generator. The ideal is some compromise in which the land is used in a responsible way that also preserves biological diversity.

Finally, it is important to distinguish between individual small owners and the large timber corporations that rival some national governments in the size of their landholdings. Arguments for preserving the freedom of small forest owners do not justify laissez-faire policies for large corporate landowners. Corporate managers’ personal freedoms are not at stake in the same way, and their management decisions have vastly greater effects on natural and human communities. No government that cares about preserving its citizens’ biological heritage will fail to regulate the environmental impacts of large corporate landowners.

### C. Wilderness in Less-Developed Countries

Recently, some writers have argued that biodiversity preservation is a specifically North American or West-
ern preoccupation, whose promotion in less-developed nations amounts to cultural imperialism. According to Ramachandra Guha, for example, wilderness preservation is inappropriate and unnecessary in these countries, whose peoples face more pressing environmental issues centered on meeting basic human needs. He argues that:

the setting aside of wilderness areas has resulted in a direct transfer of resources from the poor to the rich [in the less-developed nations]. Thus, Project Tiger, a network of parks hailed by the international conservation community as an outstanding success, sharply posits the interests of the tiger against those of poor peasants living in and around the reserve. The designation of tiger reserves was made possible only by the physical displacement of existing villages and their inhabitants; their management requires the continuing exclusion of peasants and livestock... transplant[ing] the American system of national parks onto Indian soil. In no case have the needs of the local population been taken into account, and as in many parts of Africa, the designated wildlands are managed primarily for the benefit of rich tourists. (Desjardins, 1999)

There is some truth in Guha's claims. Several of Project Tiger's reserves were built around old hunting preserves from which the poor had long been excluded, while others were set up on former state or communally owned lands and displaced numerous villages, causing real hardship to thousands. Grazing and tree cutting in the core areas of the reserves were prohibited, both to limit human-tiger conflicts and to preserve a more complete flora and fauna.

On the other hand, India's wild tigers were clearly headed for extinction when Project Tiger was undertaken: between 1900 and 1972, the year it was initiated, the tiger population fell from tens of thousands to just 1800 individuals. Strictly limiting tiger hunting had not halted this decline. Habitat conservation was clearly necessary to protect the tigers over the long term and, given the requirements of tigers and their inevitable conflicts with humans, this had to involve some displacement and restrictions on local inhabitants.

Should Project Tiger have been attempted? Guha suggests not: he believes it represented an unjust appropriation of the resources of poor people. At the same time, a focus on tigers went hand in hand with ignoring environmental problems that impinge far more directly on the lives of the poor—e.g., fuel, fodder, water shortages, soil erosion, and air and water pollution... [which are] far more pressing environmental problems within the Third World (Desjardins, 1999). Others disagree, arguing that habitat preservation and restrictions on human economic use of this habitat were necessary and appropriate responses to the imminent extinction of the Bengal tiger. This would have been a great cultural loss to the Indian people and an unjust destruction of an intrinsically valuable species. Many conservationists do not accept the extinction of species as a 'less pressing' problem than those mentioned by Guha, because they do not accept his exclusive focus on human interests, nor his narrow definition of those interests (Fig. 5).

Recently, wildlife managers in the less-developed countries have been experimenting with ways to give local people a stake in the success of wildlife and park conservation, with encouraging results. In Africa, these efforts have included disbursing a percentage...
of park revenues directly to local villages, increasing efforts to hire locals as guides and forest wardens, compensating for crop damage done by wildlife straying outside of parks, and giving local people input into protected areas management. In India, beginning in the late 1980s, the Ramnabinhore Foundation and other groups began work to promote sustainable development in the villages on the periphery of the Project Tiger reserves. This has included replanting denuded forests and improving fodder—to decrease pressure to graze and cut firewood within the reserves—as well as efforts to educate local children in natural history and conservation principles.

Justice demands that local people be treated with respect and their interests considered in all programs to protect wildlife and wildlands. Such respect and consideration will not solve all problems, however, particularly in a country as overpopulated as India, whose human population has increased from 280 million to 910 million in this century. In some instances, if we want to preserve wildlife, we will have to sacrifice human interests.

Overall, securing human rights and furthering essential human interests should strengthen efforts to preserve biodiversity. The United Nations General Assembly has affirmed that all human beings have fundamental rights to clean air, clean water, pure food, and a healthy environment generally. The measures needed to secure these human rights would also benefit wildlife and natural systems. Environmentalists have argued that future generations have a right to an undiminished natural heritage. Respect for this right would halt many environmentally destructive development projects. Natural areas are often threatened by remote governments and corporate managers, while their strongest defenders tend to be local inhabitants who know and love these areas. Securing political rights and economic justice for local inhabitants should help preserve these areas.

VI. THE IDEAL OF THE CONSERVATION BIOLOGIST

Four hundred years ago, modern science's great pioneer and prophet Francis Bacon located the primary value of science in its creation of a powerful technology for controlling nature. "The End of our Foundation is the knowledge of Causes, and secret motions of things," Bacon wrote in The New Atlantis, "and the enlarging of the bounds of Human Empire, to the effecting of all things possible." Without denying science's utilitarian benefits, conservation biologists attempt to move in a different direction, developing the knowledge needed to preserve nature rather than to change, control, or exploit it.

Both historical and contemporary examples attest that science can be carried out in this spirit. Aldo Leopold and Rachel Carson, Paul Ehrlich and E. O. Wilson, and many others from a wide variety of disciplines and backgrounds have combined contributions to science, literature, education, public policy, and conservation. The challenge for the scientist is to personally cultivate a loving knowledge of nature and to speak about nature in a way that promotes its celebration and protection (Fig. 6).

A. Professional Decisions

If conservation biologists are to help successfully preserve biodiversity, they must take on several active roles in addition to their scientific pursuits. For a start, they must become more effective educators in public forums. Conservation biologists often teach college students and
write technical papers addressing environmental issues, but they need to reach a wider range of people by also speaking in villages, elementary and secondary schools, parks, and neighborhood gatherings. They must spend more time writing articles and editorials for newspapers and magazines, as well as speaking on radio, television, and other mass media. Because tenure, promotion, and professional prestige often accrue for technical work and peer-reviewed science but not for more popular and disseminative work, conservation biologists may face difficult choices when deciding whether to devote time to the latter.

Similarly, research projects describing habitat requirements or methods of transplating an endangered species may have important conservation implications, but little potential to make basic advances in ecological or biological theory. Again, hard choices between professional glory and conservation usefulness may be necessary. As conservation biology becomes more established as a discipline, the system of rewards in place for practical conservation work will hopefully improve. Tenure and promotion committees at universities should acknowledge the value in community outreach and research that addresses local conservation issues.

Conservation biologists must also become politically active. Involvement in the political process allows conservation biologists to influence the passage of new laws to support the preservation of biological diversity or to argue against harmful legislation. Though much of the political process is time-consuming and tedious, it is often the only way to accomplish major conservation goals, such as acquiring new parks and reserves. Conservation biologists need to master the language and methods of the legal process and form effective alliances with environmental lawyers, citizen groups, and politicians. With their detailed knowledge of specific organisms and ecosystems, biologists are well placed to alert the public to the threats to biodiversity. They may also present this natural heritage in an appealing and inspiring way that leads to its preservation.

Such outreach and activism take time away from the pursuit of pure science. But many believe that at this point in human history, we no longer have the luxury to pursue knowledge for its own sake. To learn about biological diversity today is to learn about the threats facing it. These threats demand an active response.

Fortunately, there is room for many types of work within conservation biology. Field and laboratory biologists who perform detailed natural history studies and genetic analyses on endangered species are necessary; so are hands-on managers who put together species recovery programs and coordinate interagency partnerships to facilitate them; so are teachers and writers who popularize wild nature; and so are political firebrands who alert the public to biodiversity losses and corporate environmental crime.

B. Personal Choices

What about conservation biologists’ private lives? Should a conservation biologist own a sports utility vehicle, for example? It gets terrible gas mileage, yet it might greatly facilitate her field work. Should a conservation biologist take a spectacular eco-tourist vacation to Amazonia? The trip uses prodigious resources, yet he might gather information and take slides to educate audiences back home about important environmental issues. Then again, such reasoning may hide our real motivations: to drive in maximum comfort, to travel and enjoy ourselves. There is nothing wrong with comfort and enjoyment per se, but such high-consumption activities take a great toll on world biodiversity. Perhaps a conservation biologist should set a more restrained example.

Integrity is a key human virtue. It means living in conformity with our values and resolutely striving to toward worthwhile goals. As spokespeople for biodiversity protection, conservation biologists will make more converts if they practice conservation in their own lives. Above all, this means limiting their personal consumption of resources through owning fewer things, recycling, using public transportation, and taking other appropriate actions. However, it is not necessary to put on a hair shirt or engage in a quest for absolute purity. Showing that a life devoted to conservation can be stimulating and enjoyable is itself an important conservation message.

Should a conservation biologist dive into political debates? Give up time in the lab to meet with a group of concerned citizens? Drive a car to work? Eat meat? Have children? These difficult professional and personal questions must be faced by conservation biologists and other committed conservationists. Responses may legitimately differ, but we should not forget that the fate of world biodiversity depends, in part, on our answers.

I. Historical Development of Ethnobiology

II. Current Trends in Ethnobiology

III. The New Synthesis

GLOSSARY

analysis, emic and etic  Concepts derived from the linguistic terms “phonetics” (representing speech sounds by precise and unique symbols and by technical descriptions of articulation, as practiced by trained linguists) and “phonemics” (characterization of speech through a minimal number of symbols, typically recognized by the speakers of a language). By extension, etic refers to the external explanation of cultural knowledge and practice (such as the use of Linnean taxonomy or scientific nomenclature to describe local useful plants), whereas emic denotes the internal perspective of local people (e.g., ethnobiological categories and nomenclature).

economic botany  As originally conceived, a branch of applied botany that arose during the colonial period to identify and characterize economically important plants and the products derived from them. Currently, it is a scientific endeavor that seeks to document the properties of useful plants through agronomic, archaeological, ecological, ethnobotanical, genetic, historical, phytochemical, and other empirical approaches. It overlaps broadly with ethnobiology because both fields have witnessed a similar development in theory and methodology in recent years.

ecosystems, anthropogenic and natural  Communities of organisms and their environment formed either through human action or through natural processes. In practice, it is difficult to establish the extent to which an ecosystem is anthropogenic or natural, reflecting the current and historical impact of people on the environment.

ethnobiology  A term coined in 1935 that has been defined as the study of the reciprocal interactions between people and the biological organisms in their local environment and, recently, as the study of biological sciences as practiced in the present and the past by local people throughout the world. Many researchers consider that ethnobiology comprises numerous subfields, such as ethnobotany, ethnoecology, ethnoscience, and ethnozoology, but there is no consensus on this point.

ethnobotany  and ethnozoology  Approaches to studying the reciprocal interactions between people and the plants and animals in their local environment. This definition has been criticized as broad and open-ended, but it captures the common goals of analyzing traditional biological knowledge and assessing human impact on the environment. These approaches include subfields such as paleoethnobotany and paleoethnozoology, which evaluate archeological evidence on the past interactions between people, plants, and animals.
ethnoecology. Typically defined as the study of local knowledge and management of ecological interactions. Recently, some researchers have proposed an alternate definition, considering ethnoecology as an emerging field that focuses on local peoples’ perception and management of complex and coevolved relationships between the cultural, ecological, and economic components of anthropogenic and natural ecosystems. It is concerned with the interaction between knowledge, practice, and production, and it is oriented toward applied research on conservation and community development.

ethnoscience. Arose as a minor subfield of ethnography concerned with recording in great detail local peoples’ knowledge of biological organisms and the physical environment. Later, the term came to be used in a more restricted sense by cognitive and linguistic anthropologists to refer to local classification systems (as an object of study) and their semantic analysis (as a methodological approach). In France, the term is used to refer to ethnobiological studies in general.

indigenous, local, and traditional. Adjectives used by anthropologists, ethnobiologists, and other academics to describe people, practices, and knowledge. Indigenous denotes people (and their cultural practices and knowledge) who claim to be the original or long-term inhabitants of a particular place, in contrast to more recent colonizers. Traditional refers to established lifestyles, practices, and beliefs that guide cultural continuity and innovation—a definition that recognizes that traditions are always in a process of adaptation and change. Local, preferred by many researchers because it is the broadest and least value-laden term, indicates cultures that are found in a specific part of the world. It is commonly used to refer to people, whether long-term residents or recent arrivals (rural or urban), who make a living from the land and are knowledgeable about the biological resources in their environment.

ALTHOUGH THE. 100th anniversary of ethnobotany (coined in 1896), the golden anniversary of ethnobiology (first used in 1935), and the silver anniversary of ethnoecology (appearing in 1954) have passed, there is no consensus on the precise definition of these fields. This is explained in part because of their relatively recent origin and the current surge in their theoretical, conceptual, and methodological refinement. Disagreement over definitions is typical of multidisciplinary fields; in the words of Brent Berlin, ethnobiology “combines the intuitions, skills, and biases of both the anthropologist and the biologist, often in quite unequal mixtures.”

In one sense, ethnobotany, ethnobiology, and ethnoecology are new terms for old practices. People have been exploiting the usefulness of diverse plants, animals, and ecosystems since the dawn of humanity. Documentation of local people’s perception of the environment emerged slowly over thousands of years as scholars from many cultural traditions recorded local ways of classifying and using plants and animals. The onset of European colonization of Africa, Asia, the Pacific, and the New World gave added impetus to the study of local knowledge of tropical and temperate organisms and ecosystems.

Toward the end of the nineteenth century, academics began to use the prefix ethno- to refer to the way that local people view the natural world, in contrast to the perspective of natural scientists trained in universities. They coined terms such as “ethnobotany” (first used in print by Harshberger in 1896) and “ethnozoology” to describe these emerging fields of study that crossed the boundaries of natural and social sciences. Interest in traditional environmental knowledge continued apace in the early twentieth century, and in 1935 Castetter coined the term “ethnobiology,” setting as its agenda the systematic analysis of data collected by ethnobotanists and ethnozoologists to achieve a deeper understanding of local peoples’ knowledge and lifestyles. Economic botany gained importance as a parallel field focused on useful plants and the products derived from them. In 1954, Harold Conklin proposed the term “ethnoecology,” originally conceived as a holistic and integrated approach to understanding local ecological knowledge and practice on their own terms, even while drawing on the concepts and methods of diverse scientific disciplines. A focus on classification systems and the linguistic and anthropological methods used to analyze them gave high visibility to an approach called ethnoscience.

In the 1980s and 1990s, further development of these various lines of research gave rise to new definitions, innovative theoretical orientations, and sophisticated qualitative and quantitative methodological approaches applied to local knowledge of the environment. In addition, ethnobiology expanded beyond its original geographical borders as the field gained importance in countries such as China, India, and Mexico. There is currently a new synthesis emerging—as yet without consensus—that defines ethnobiology as the study of biological sciences as practiced by local people through-
out the world, comprising both empirical knowledge (savoir) and technical know-how (savoir-faire), and inclusive of subfields such as economic botany, ethnobotany, ethnology, and ethnozoology.

I. HISTORICAL DEVELOPMENT OF ETHNOBIOLOGY

Despite the insights provided by archaeological and historical linguistic studies, setting an even approximate date of the emergence of local biological knowledge is a matter of opinion. A detailed understanding of the natural world was key to the independent emergence of plant and animal domestication over a period ranging from 8500 B.C. in southwest Asia to 2500 B.C. in the eastern United States. However, environmental knowledge reaches even further back into history, when hunting and gathering dominated subsistence activities.

Some researchers would place the beginning of human ecological knowledge at the dawn of humanity, approximately 7 million years ago. Early human ancestors, who lived on the African continent 2.5 million years ago, apparently fashioned stone tools for harvesting and processing food, probably allowing them to adapt to new environmental conditions. It is widely assumed that humans have been observing natural phenomena, distinguishing between biological organisms and discovering their uses ever since the emergence of Homo sapiens approximately 500,000 years ago. The archeological record reveals that by 500,000 years ago, Cro-Magnons had developed technologies for construction, fishing, gathering, and hunting that were dependent on a detailed understanding of plants, animals, and other elements of the natural environment.

Just as no one knows exactly when ecological knowledge appeared on the cultural landscape, there is no clue when the original precursors of ethnobiologists came on the scene. The first critical observations of other peoples’ ways of perceiving nature are probably as old as culture contact itself. Because these observations went unrecorded, the origin of the study of traditional knowledge reaches even further back into history, when hunting and gathering dominated subsistence activities.

Some researchers would place the beginning of human ecological knowledge at the dawn of humanity, approximately 7 million years ago. Early human ancestors, who lived on the African continent 2.5 million years ago, apparently fashioned stone tools for harvesting and processing food, probably allowing them to adapt to new environmental conditions. It is widely assumed that humans have been observing natural phenomena, distinguishing between biological organisms and discovering their uses ever since the emergence of Homo sapiens approximately 500,000 years ago. The archeological record reveals that by 500,000 years ago, Cro-Magnons had developed technologies for construction, fishing, gathering, and hunting that were dependent on a detailed understanding of plants, animals, and other elements of the natural environment.

An overview of these early texts and later works reveals that ethnobiology and natural history have evolved—much like the biological species and ecosystems that are their focus—through a process of punctuated equilibrium. Certain historical periods are marked by an intensive effort to expand empirical knowledge of natural phenomena, often by incorporating local lore, whereas other epochs are characterized by an unquestioned acceptance of published works.

A. Early Scholars in Europe

Academics often trace their intellectual history to the era of Greek philosophers, who lived more than 2300 years before our time. This is when classical botany and zoology were brought into existence by scholars such as Aristotle, who sought to summarize all current knowledge about plants and animals in encyclopedic works. It was as part of this endeavor that scholars in Europe first made a systematic study of what local people knew about the environment. In part, Aristotle and other early naturalists such as Theophrastus—who, as author of De Historia Plantarum and other works, is considered the father of botany—rejected many local supernatural beliefs in their quest to understand the natural world. Simultaneously, they drew on commonsense explanations and empirical knowledge of local people when describing the classification and use of plants and animals.

Among the people who followed in the footsteps of these early naturalists is Dioscorides, a military physician born in Asia Minor in the first century B.C. He wrote De Materia Medica, a treatise on medicinal plants which was the standard reference of botanists, medical doctors, and other scholars in Europe for 1500 years.

Apart from drawing on previous herbals, Dioscorides learned much about herbal remedies by interacting with local people he encountered during his wide-ranging travels with the Roman army in the Mediterranean region. Pliny the Elder, a Roman scholar who was one of Dioscorides’ contemporaries, recorded extensive plant lore in his 37-volume encyclopedia called Historiarum mundi or Natural History. He devoted 9 volumes to medicinal plants, making frequent reference to traditional practices and knowledge.

B. The Doldrums of the Middle Ages

The documentation of local knowledge that marked the origin of biological thought in Greek and Roman Antiquity was much less evident in the Middle Ages in Europe. The decline of the Roman Empire virtually
halted scholarly research on natural history and resulted in the destruction of much existing literature of the epoch. Throughout the Middle Ages, Europeans based their studies of medicinal plants almost entirely on the works of Theophrastus, Pliny, Dioscorides, and other early naturalists. Physicians from across the continent relied heavily on De Materia Medica, often trying unsuccessfully to match the local flora to the approximately 600 Mediterranean species described by Dioscorides instead of documenting the popular knowledge of their own region. As anthropologist Scott Atran (1990) summarized,

After Aristotle, the practice of copying descriptions and illustrations of living kinds from previous sources superseded actual field experience in the schools of late antiquity. Well into the Renaissance, scholastic “naturalists” took it for granted that the local flora and fauna of northern and central Europe could be fully categorized under the Mediterranean plant and animal types found in ancient works. Herbs and bestiaries of the time were far removed from any empirical base.

C. The Golden Age of the Moors

Despite this stagnation on the part of European scholars, general knowledge of medicinal plants was enriched by the flow of information coming from the Arab world, particularly through Spain (Andalucia). Sicily, and North Africa. Although dedicated in part to translating the works of Aristotle, Theophrastus, Dioscorides, and other classical writers, Moorish and other medieval scholars in these regions pursued empirical research that they applied to practical ends in agriculture, astronomy, botany, mathematics, medicine, and other fields. Although there are records of Arabic writings on botany dating to the ninth century, it was particularly in the twelfth and thirteenth centuries that scholars became prolific in recording precise original observations on plant and animal biology, conducting experiments on agricultural crops, and attempting to classify plants systematically. One of the key early scholars was Abū-l-Kheyr Al-Ichābi, apparently the “anonymous botanist of Seville” of the latter half of the twelfth century who wrote the Umdat at-tabīb, a botanical treatise that contains detailed descriptions of the anatomy, habitat, and local names of plants. Maimonides, a Jewish scholar resident in southern Spain during the twelfth century, contributed works such as Book Explaining Medicinal Drugs and Treatise on Poisons. The thirteenth century brought the works of Rachid-ed-din Ibn Es-Sirri in the Maghreb (western Arabic region) by Abū-l-Abbas En-Nahāti—who documented local plants and their uses during his extensive travels in what is now Spain, North Africa, Syria, and Iraq—and later scholars such as his student Ibn Al-Bayan, author of the Treatise on Simples or Jami’ al-mufradat, which contains information on the synonymy (including Berber and other local names), description, properties, and uses of approximately 1400 species. Throughout this period, descriptions of specific plants were drawn from multicultural sources, including Berber plant knowledge and the traditional practices of Jewish pharmacists who lived throughout Europe and North Africa, passing their profession from one generation to the next. As the Moors were forced from Andalucia and other parts of Europe, Arab science fell into decline. Later botanical treatises, including the Ḥadīqat al-azhār of the sixteenth century Moroccan scholar and medical doctor Al-Wazir Al-Ghassani, were largely based on the Umdat at-tabīb and other early works.

D. Scholars from Other Cultural Traditions

A similar pattern of initial empirical discovery and cross-cultural learning mixed with centuries of uncritical acceptance of written works is evident in other cultural traditions. In China, the first scholarly studies of traditional biological knowledge are thought to date at least to the fifth century B.C., approximately 200 years before early Greek philosophers began recording their ideas about botany and medicine. During this epoch, the Chinese philosopher Confucius is said to have encouraged his students to study ancient knowledge, including traditional names of plants and animals. In the first or second century A.D., about the time that Dioscorides was alive in the Mediterranean, Chinese scholars published the first of many materia medica, referred to generally as bencao (from a combined term for tree and grass) in Chinese, which contain information on minerals, plants, and animals used traditionally in the treatment of illness. Medical doctors of the fifth
or Gangmu began in India during the sixth century B.C. and spread by traveling to the countryside to talk with people. He obtained not only by studying ancient texts but also information on more than 10,000 herbal remedies that many centuries before. His major work, the Bencao Gangmu or Compendium of Materia Medica, contains information on more than 10,000 herbal remedies that he obtained not only by studying ancient texts but also by traveling to the countryside to talk with people.

Ayurveda, a system of medicine which putatively began in India during the sixth century B.C. and spread to Sri Lanka by the third century B.C. and into Tibet by the seventh century A.D., was partially based on traditional knowledge. According to folklore, shepherds and forest dwellers familiar with the types and properties of medicinal plants first discovered the remedies used in this oriental medical practice. Their knowledge was discussed in various literary religious works called vedas (from the Sanskrit word for knowledge), which were apparently written in India approximately 3200 years ago, after millennia of oral transmission. Ayurvedic scholars later compiled additional empirical observations in a series of books referred to as the Nigh- ants, or Vedic glossaries. During the subsequent period of foreign domination and internal conflict that brought innovation and documentation of local knowledge to a standstill, these standard texts of ayurveda remained unchanged.

Other ancient written sources that document local biological knowledge were in part the product of culture contact and changes in political and economic dominance. In the New World, for example, the Aztecs broadened their own sophisticated knowledge of medicine and agriculture as they sought tribute and learned of new useful plants from the different Mesoamerican cultures they conquered. The Aztecs cultivated many newly discovered species in extensive highland botanical gardens tended by people from various geographical regions of Mesoamerica. The depth and richness of the preconquest indigenous knowledge of the natural world are demonstrated by scholarly works, including the Biduaras Manuscript, an illustrated herbal written in 1552 by two Aztecs who had been educated by Catholic missionaries. One author, Martín de la Cruz, was an indigenous physician who had acquired his medical knowledge empirically. The Mayas and Incas had similar literate traditions and they doubtlessly recorded some aspects of the ecological knowledge of the various ethnic groups they dominated at the height of their political power and cultural development. Many of these New World written sources of local knowledge were victims of the conquest, destroyed by overzealous missionaries and conquerors who wished to impose European culture, languages, and religion on the people of the New World.

E. The Renaissance and Exploration

During the sixteenth and seventeenth centuries, Renaissance botanists began to emulate the methods that Dioscorides had applied approximately 1500 years previously, bringing an end to the intellectual stagnation that characterized the Middle Ages in Europe. They carefully observed plants in the field and inquired about their local names and uses in Germany, Holland, Italy, and other parts of Europe. This experience served them well when faced with the influx of exotic species from areas of the world discovered and colonized by Europeans during this period. The diversity of biological organisms discovered by explorers stimulated Linnaeus, Darwin, and other natural scientists to formulate many of the concepts that are the building blocks of modern-day systematics and evolutionary studies. Although Linnaeus left some notes and sketches on the use of plants by local people, his greatest contribution to the future field of ethnobotany was the incorporation of notions of folk biology and nomenclature, including the concept of morphological affinity as a criterion for defining taxa, in the scientific classification of plants.

This Renaissance was the golden age of the European herbals. The shift from manuscripts (produced by hand) to wood-cut and metal-engraved herbals published in large numbers allowed new botanical knowledge to be disseminated widely. The quest to exploit local knowledge and economically important species which went along with coloniza-
tion inspired adventurers, missionaries, and natural historians to record their observations on traditional biological knowledge in many parts of both the New World and the Old World. As ethnobotanist Richard Ford (1978) described,

A rapid progression of expeditions came to North America to discover and to colonize, and the chronicles of adventure are a record of the utilitarian value of an unfamiliar landscape and the use the indigenous people made of it. Its economic potential certainly had priority to any interest in
attitudes about the land. The observations... provided the first natural history of North America and the bases for the beginning of ethnobotany.

From the sixteenth century onwards, researchers began to focus increasing attention on the biological wealth of tropical countries and the benefits it promised for Europeans. To this end, scholars drew on the knowledge of local people, who continually experiment with cultivated and managed species in anthropogenic ecosystems and wild plants harvested in natural ecosystems. Scholars consulted both written sources, such as Ayurvedic works and Chinese pharmacopoeias, and oral history to produce extensive encyclopedias of useful plants from around the world, ranging from the *Coloquios dos simples e drogas da India*, written by the Portuguese explorer Garcia ab Orta in 1563, to the 12-volume *Historia Malabarica* of Van Rheede published in the late 1700s and *A Dictionary of Economic Products from the Malay Peninsula* produced in 2 volumes by Burkhill in 1935.

Another notable example is the herbal of Rumphius, a seventeenth-century natural historian from Germany who spent nearly 50 years in Asia working for the Dutch East-Indies Company. Increasingly released from his administrative duties but still under the employ of the company, he focused his attention on studying useful plants, animals, and minerals in various regions that today constitute Indonesia. He provided descriptions of more than 700 medicinal or toxic plants, published posthumously in the six volumes of the *Herbarium Amboinense*.

**F. Creation of New Fields**

Although Rumphius and his counterparts approached natural history as a holistic phenomenon, scholarly activity in later centuries began to reveal a fragmentation of research into distinct disciplines, marking the beginning of reductionism in the sciences. Subdivisions of science became more clearly defined, and professional practitioners began to specialize in specific subfields. Theoretical science was increasingly applied to technological innovation, stimulating the growth of educational institutions and commercial enterprises. Theoretical science, including botany, zoology, pharmacognosy, and other fields, began to mature into distinct disciplines, each with separate methods and goals. Scott Atran (1990) characterized this as the “breakaway of science,” a time when natural historians began to leave behind commonsense descriptions of natural phenomena—drawn in part from local peoples’ perception and classification of nature—in order to embrace rigorous experimental methods. Social scientists began to focus on separate aspects of human society and culture, with
the consequent emergence of fields such as anthropology, linguistics, and sociology.

2. Economic Botany

Nineteenth-century botanists, who focused primarily on the utility of plants and only secondarily on local culture, began to refer to their approach as economic botany. The goal of their research has been to document local uses of plants and to organize the resulting data according to the global system of plant classification. They have produced detailed works on plants employed by local people for food, medicine, textiles, utensils, and many other purposes (Schultes and Raffauf, 1990).

Research on the commercial value and utility of plants expanded as botanists from the United States and Europe explored the New and Old World tropics in search of products that would increase the wealth of developed countries and the well-being of people in general. Today, economic botanists continue to search for marketable products in tropical forests and elsewhere, but they are increasingly interested in how the commercialization of these resources can contribute to resolving the poverty, malnutrition, and diminished social status of local people as well as spurring economic development in developing countries. An increasingly important offshoot of this enterprise is bioprospecting (a term derived from “biodiversity prospecting”), the search for useful and novel products (including chemical constituents of medicinal value) from plants, animals, fungi, and other biological organisms. Other economic botanists are concerned with developing theoretical and methodological approaches to understanding the subsistence and commercial value of plant resources, now and in the past.

3. Ethnoscience

While botanists were establishing economic botany, anthropologists and other social scientists were developing a different perspective. In the tradition of ethnography developed by anthropologist Franz Boas, ethnoscience emerged as a minor subfield dedicated to recording in minute detail local peoples’ knowledge of biological organisms and the physical environment. The subfield underwent a further transition in the 1950s and 1960s, when cognitive and linguistic anthropologists began to focus on the empirical categories, social rules, symbolic systems, and modes of behavior that reflect how local people perceive the natural world. These early ethnological studies formed the foundations for a new ethnoscientific approach that advocated rigorous analyses of ethnobiological knowledge, with particular emphasis on systems of ethnobiological classification. Thus, whereas economic botany emerged as a utilitarian practice firmly rooted in commerce and development (and later developed theoretical frameworks), ethnoscience arose as an intellectual endeavor oriented toward a deeper understanding of human culture and cognition.

4. Ethnoecology

Even though he is most associated with the development of the ethnoscientific approach, Conklin is credited with coining the term ethnoecology in 1954. Given the precedent set by terms such as ethnobotany and ethnoecology, it would be natural to assume that ethnoecology would refer to the study of local perceptions of ecological processes, such as nutrient cycling, vegetational succession, or the interactions between plants and animals. An increasing number of researchers propose a different definition, using the term to refer to local peoples’ perception and management of the complex and coevolved relationships between cultural, ecological, and economic components of anthropogenic and natural ecosystems. This emerging subfield, much as the broader field of ethnobiology, is concerned with the interaction between knowledge, practice, and production and is oriented toward applied research on conservation and community development. Mexican ecologist Victor Toledo stated that the aim of ethnoecology should be the ecological evaluation of the intellectual and practical activities that people carry out during their appropriation of natural resources.

Although the definition of ethnobiology includes a reference to knowledge and know-how (savoir and savoir-faire), for ethnoecologists the distinction is between an ethnobiological corpus, local peoples’ repertoires of concepts, perceptions, and symbolic representations of nature, and praxis, the art, science, and skill of appropriating nature and biological resources. The interrelationship between knowledge and practice is manifested in production, as people apply their intellectual understanding of nature to the everyday tasks of farming, gathering, and hunting for subsistence and commercial purposes. In order to understand these complex interactions, ethnoecologists seek to elucidate how the management of anthropogenic and natural ecosystems—and the biological organisms they harbor—has arisen through a process of coevolution between the environment, knowledge, technology, social organization, and values of local peoples.

Although attractive conceptually, the development of this conception of ethnoecology has been limited
by the lack of a unifying theoretical framework and a practical methodology. This distinguishes it from ethnobiology, which is developing a central organizing theory, an orientation toward hypothesis testing, and an increasingly elaborate set of qualitative and quantitative methods, drawn in part from ethnobotany, ethnozoology, and economic botany.

5. Ethnobiology

Clement (1998) proposes that the starting point for ethnobiology—as the field which integrates related approaches such as economic botany, ethnobotany, ethnozoology, and ethnoscience—is the 1860s, when the first designations for the field began to be used by American and European scientists. In a historical sketch that spans a period of more than 130 years, he discusses the origins, key theories, and methodological approaches of the main trends of ethnobiology. Although no such historical framework of a scientific discipline is without controversy and potential modification, Clement’s synopsis is a serious effort to provide a detailed historical analysis of ethnobiology.

Clement divides the development of the discipline into three eras and seven periods (Table I). The preclassical period, from 1860 to 1953, is dedicated to gathering empirical data on the uses of plants and animals from an etic perspective and to the first syntheses that begin to define the scope of the discipline. During the classical period (1954–1980), there is a shift to studies carried out from an emic perspective and a particular focus on ethnobiological classification. An increase in collaborative work between academic specialists and local people and the formation of professional associations of ethnobiology characterize the postclassical period, from 1981 to the present. Later in the period, there is an increased focus on the appropriation and management of plant and animal resources and a concern for application of research results to the resolution of environmental and social problems. This historical review provides an appropriate starting point for considering the current trends in basic and applied ethnobiological research.

II. CURRENT TRENDS IN ETHNOBIOLOGY

Recent studies in ethnobiology can be classified in three general, interrelated areas. Documentation and analysis of uses of plants and animals is the oldest aspect of ethnobiology. A focus on knowledge, which became especially popular in the 1950s and 1960s, characterizes the study of perception and classification of the natural world. In the 1980s and 1990s, attention shifted to local management of biological resources and the environment, often drawing on ecological concepts and methods. These areas are combined in various degrees in the following major trends in ethnobiological research.

A. Cognitive Mapping

Ethnobiologists have documented local peoples’ spatial conceptualization, including their ability to locate biological resources, discern landscape features, and identify different types of vegetation. This geographical literacy is linked to an aptitude for assessing the potential productivity of the environment, often through the recognition of plant species that indicate fertility or sterility of soils. This expertise derives in part from local peoples’ sophisticated perception of how the various elements of the ecosystem (organisms, soils, climate, topography, etc.) form an interdependent whole. In addition, it is derived from their classification of key geographical landmarks that are labeled by specific toponyms, or geographical place names. Local views of the landscape are being integrated into geographical information systems, which in turn are useful in creating biological resource maps and management plans for specific areas. When united with ethnobiological inventories and studies of local categorization of ecological succession, community mapping allows researchers to test hypotheses on whether the highest number of useful plants and animals come from primary or secondary forest, or anthropogenic versus natural ecosystems.

Local peoples’ mastery in selecting plant populations that yield the best fruit, the most potent medicine, or the best materials for construction is attributed in part to their grasp of the landscape. These mental maps also explain their adeptness at selecting the best place to cultivate the earth, create human settlements, or leave natural areas that maintain soil fertility, water purity, and other environmental benefits. Researchers have demonstrated that these skills can degenerate when local people find themselves pressured by economic needs to overexploit the resources available to them or are forced onto lands for which they are maladapted culturally.

The ability of some local people to integrate and recall complex information on the local environment often gives them special proficiency as stewards of community reserves and other protected areas. Their ability to assess the quality of useful biological resources and to locate areas where these organisms are found in

* Adapted from Clément (1998).
about the classification of specific cultural domains, practices, and production, ethnobiologists assess the value of anthropogenic and natural ecosystems and the rationality of resource harvesting decisions made by small-scale farmers and gatherers of forest products. Much of this research is carried out in 1-ha plots, agricultural fields, home gardens, and other measured study sites, resulting in quantitative assessments of sustainability and value. These methods allow researchers to evaluate the hidden costs of tropical forest destruction, the economic benefits derived from both subsistence and commercial use of wild species, and the environmental advantages of maintaining forest cover as a way of buffering local climate and preserving the purity of local air, water, and soil. Through these perspectives, conservation biologists, development specialists, and communities monitor the sustainability of current productive practices, propose new methods of managing fields and forests, and select new biological species that can be domesticated, cultivated, or gathered locally. Studies of local systems of resource management can also enrich the work of ecologists, who seek to restore the diversity and value of forest ecosystems damaged by mismanagement or natural catastrophes. In addition, evidence of long-term management of biological organisms and ecosystems reinforces local peoples’ claims for traditional resource rights, including just compensation when novel biological resources are commercialized.

C. Scientific Covalidation

A key activity of ethnobiologists is to understand the rationale behind the way local people interact with the natural environment. In research laboratories, scientists carry out a broad array of analyses that seek to corroborate the efficacy of local uses of plants and animals, ranging from the identification of active compounds in medicinal plants to appraisal of the tensile strength of natural fibers and assessment of the nutrient content of wild foods. In the field, ecologists assess how the yields of agroecosystems compare with those achieved by large-scale monocultures and to what extent traditional methods of wildlands management are sustainable. Ethnobiologists compare ethnobiological categories with scientific taxa, judging the extent to which local biological classifications correspond to biosystematics. This range of activities is aimed at revealing the complex interrelated sets of categories for plants, animals, soils, climates, vegetation, illnesses, food, and other cultural domains and natural phenomena.

Much attention has focused on describing universal similarities in the ways in which local people perceive the natural world. Many generalizations on the categorization, naming, and identification of plants and animals are now widely accepted, whereas others continue to provoke controversy, especially among anthropologists who place emphasis on cultural relativity or the uniqueness of each ethnic group. In particular, there is disagreement over why people are motivated to classify and name plants and animals, soils, and other natural features. Those who follow an intellectualist line of reasoning argue that there is a universal human tendency to categorize plants and animals according to their overall appearance or symbolic role. These researchers note that local people tend to group organisms with a similar morphology or behavior, regardless of their cultural utility. In a similar vein, some colleagues propose an ecological rationale, noting that some aspects of ethnobiological classification can be elucidated by reference to the role and interaction
of plants and animals in diverse ecosystems. Although there is an emerging consensus that classification is motivated by a combination of these factors, there continues to be much debate about which is the most important dimension.

Studies of ethnobiological classification contribute to understanding—in part by reference to the global system of plant systematics—how local people perceive and manage natural resources. When carried out in a participatory way, ethnobiological inventories provide an opportunity for local people and researchers to work together to document the distribution, management, and use of biological resources locally and globally. They produce the baseline data needed to produce bilingual and bicultural manuals that compare and contrast different ways of classifying, managing, and using biological organisms. These ethnobiological manuals contribute to applied programs of conservation and development by highlighting culturally significant species that local people are harvesting from the wild, managing in anthropogenic landscapes, or cultivating in gardens and fields. Often, these species are selected for use in initiatives that promote reforestation, sustainable harvesting of minor forest products, or cultivation of useful plants that contribute to the well-being and income of local people.

E. Knowledge Variation

There are significant differences in the way local people perceive and use biological resources. Ethnobiological studies reveal that some plants and animals are known by a majority of the population, but others are the domain of curers, the elderly, women, or members of another social group. There are significant differences in the biological knowledge of people living in separate communities, belonging to distinct ethnic groups, speaking different languages, or subsisting in diverse ecological zones. These differences can be explained in part by the fact that each person’s knowledge is correlated with sociological characteristics such as age, gender, occupation, education, social status, and zone of residence. Perception and management of plants and animals are also affected by each individual’s life experiences—for example, if he or she has suffered from a major illness, migrated to other communities, or worked as an apprentice to a plant specialist.

Awareness of these differences is essential when assessing the depth and breadth of traditional knowledge and the diversity of ecological practices in a particular area. It is now recognized that researchers run the risk of obtaining a biased perspective of local biological knowledge if they work with few informants. In contrast, consultation with a representative cross-section of local people can provide a relatively accurate portrayal of perception of the natural world. Ethnobiologists are analyzing patterns of agreement among different individuals, producing a quantitative method of identifying the most culturally significant plant and animal species, soil types, forest zones, and other elements of the landscape. These results ensure accuracy when preparing natural resource management plans and popular manuals produced with local communities.

They can also play a role in understanding the knowledge held by specialist user groups and how they are transmitting it from one generation to the next.

F. Mechanisms of Change

Another principle that has emerged in recent studies is that knowledge about the natural environment and ways of managing biological resources are not static. They change as people move from one region to another, as youth reinterpret what they have learned from elders, and as cultures come into contact with each other. Ethnobiologists are analyzing the dynamics of these cultural changes and assessing how they can enrich or impoverish local knowledge systems.

Archaeology, linguistic reconstruction, archival research, and oral history open a window to the past, allowing researchers to discover how ecological knowledge and resource management have evolved during decades and centuries of political, demographic, and economic change. Studies of historical ecology are revealing which species, ethnobiological categories, and ecological practices have persisted, changed, or disappeared over time, including those that have become widespread through borrowing across cultural boundaries. Research that focuses on world events in recent centuries allows historians to assess the impact of colonization and other forms of culture contact on local ways of perceiving and managing the natural world.

Many regions of the world are currently in an intense period of change characterized by not only the destruction of wildlands and loss of biological diversity but also the transformation of traditional biological knowledge. In some regions, young people are not learning what their elders know about the environment, particularly as traditional ways of using biological organisms and managing natural areas fade away. Specialized knowledge held by only a few curers or spiritual leaders is lost when no apprentice is found to carry on traditional medical or religious practices. This loss of knowledge is often linked to increasing contact with national
and international cultures and is often exacerbated as local people incorporate formal education, major religions, and migration into their lifestyles. Ethnobiologists are playing a practical role in assessing the extent of cultural transformation and searching for ways of promoting the survival of local ways of classifying, using, and managing natural resources. These actions are based on the assumption that participation in the joint management of ecosystems and resources stimulates local people to retain and build on empirical knowledge and practices acquired during the tens, hundreds, or thousands of years that they and their ancestors have resided in the region. Studying the evolution of ethnobiological knowledge elucidates mechanisms of cultural resistance, allowing us to understand why local ecological knowledge persists and how we can reinforce the mechanisms of resistance. These studies also highlight the impact that local people have had on the natural environment over time, often providing evidence that they are responsible for maintaining biological diversity and stimulating innovative ideas for conservation in the future.

G. Ritual, Religion, and Symbolism

Plants and animals play an important role in rituals and spiritual practices and are a recurring element in myths, legends, and stories. Some researchers assert that local people, because of their cosmology or understanding of the universe, relate to the natural environment in ways fundamentally different from that found in, for example, European or American culture. A central element in this conception is that traditional lifestyles link people to nature in a way that provides them with a special understanding of nature. A common way for outsiders to gain access to the world of ritual, magic, and religion of local peoples is through apprenticeship with spiritual leaders, often accompanied by the use of psychoactive plants.

Whether or not these generalized notions of differences between global knowledge systems and traditional knowledge are valid in all cases, it is undeniable that spiritual beliefs about the forest and associated taboos on the use of natural resources are important elements of conservation and sustainable use of natural resources in many cultures. When people begin to abandon these beliefs, traditional controls on resource exploitation often disappear, potentially leading to devastation of formerly protected areas such as sacred groves. Ethnobiologists are increasingly aware of the need to record these belief systems and to verify empirically what impact they have on conservation and use of natural resources. In areas in which traditional cosmology is still a viable element of local culture, conservation biologists are exploring ways of integrating it with the management of protected areas.

H. The Internationalization of Ethnobiology

Although ethnobiology as an academic discipline originated in Europe and the United States, it has now been embraced by researchers in many developing countries who have subsequently adapted the techniques and concepts to their own goals and local conditions. The emergence of professional societies of ethnobotanists in developing countries, ranging from the Indian Society of Ethnobotanists in 1980 to the Asociación Mexicana de Etnobiología in 1993 and the Sociedade Brasileira de Etnobiologia e Etnoecologia in 1997, is evidence of this trend. The internationalization of ethnobiological research and training has resulted in new directions in theory and application, enriching the field. In India, the tradition of conducting ethnobotanical inventories in various tribal areas has continued, but it is now supplemented by innovative approaches to studying the harvest of non-timber forest products in joint forest management schemes and practical strategies to create community biodiversity registers. Researchers in China have contributed studies on ecological succession in swidden fields, marketing of useful plants, and analysis of agroforestry practices. Equally impressive are developments in Mexico, where ethnobiologists have focused on the management of anthropogenic and natural ecosystems as well as the process of domestication of botanical resources.

III. THE NEW SYNTHESIS

The proliferation of labels and orientations for the study of local biological knowledge and practice is likely to continue. Consensus on precise definitions will be difficult to achieve because researchers are approaching the field from a variety of academic disciplines, bringing with them a wealth of new concepts and methods. Despite this dynamic development, there is some semblance of an agreement on a typology for the discipline. Distinct approaches to gathering empirical data on the reciprocal interactions between people and biological organisms will continue to be referred to by terms such as economic botany, ethnobotany, ethnoecology,
...and ethnobotany. Ethnobotany is becoming the preferred term for an integrative discipline that draws on all these approaches to analyze traditional biological knowledge and practices throughout the world. It is unified by a central theory that local peoples’ systematic knowledge and management of biological organisms and ecosystems can be classified as biological sciences, covalidated by qualitative and quantitative research methods. Perceived in this way, ethnobotany blends conventional studies carried out by economic botanists, ethnobotanists, ethnoecologists, and ethnoscientists that present a limited vision of local people’s interaction with the natural environment. This provides an opportunity for reintegration of various disciplines of natural science, counteracting the impact of the reductionism of global scientific knowledge.

Ethnobotany seeks not only to integrate these various lines of scientific research but also to focus them on supporting community development and biodiversity conservation, which are clearly multidisciplinary endeavors. American ethnobotanist Darrell Posey argued for this style of “advocacy” or “applied ethnobotany,” whose goal is to reform the economic, environmental, and social policies that are at the root of many problems which affect people in rural and urban settings. This approach has stimulated a new generation of researchers to blend scientific research with an awareness of the loss of biotic and genetic resources, indigenous struggles for land and resource rights, and negative aspects of globalization. The ultimate goal is sustainable development, as defined by cultural, ecological, and economic parameters.

The yen for integration goes beyond creating an interdisciplinary, applied field of study. Although ethnobiologists have tended to concentrate on the empirical side of local biological knowledge, there is renewed interest in symbolic and other interpretive approaches that could give a broader view of how people perceive their natural surroundings. Many ethnobiologists advocate adopting a participatory approach through which the entire study, from research design to application of the results, is conceived as a collaborative effort between local people and researchers. These developments represent a significant achievement for ethnobotany, a field that has always sought to blend perspectives from many cultural traditions.

I. Overview

This article discusses the origin of eukaryotes, the only life-forms on Earth that are not bacteria. Eukaryotes, the one- or many-celled beings whose cells contain nuclei, can be classified unambiguously into one of four groups (or "kingdoms"): plants, animals, fungi, and protoctists. Bacteria (kingdom Monera), by contrast, are made of prokaryotic cells, whether or not their bodies are composed of one or many cells. Protoctists (kingdom Protoctista), which may be an unfamiliar term, include all those nucleated organisms that are not plants, animals, or fungi. Among the live present-day protoctists are free-living nucleated organisms such as single-celled amoebae and Paramaecium and huge multicellular seaweeds such as the giant kelp. The smaller members of the kingdom, the protozoa, are made of cells that resemble the tissue cells typical of plants and animals. Protoctista includes composite organisms—we call them the "water neithers" because they are all aquatic but are neither plant nor animal (nor fungus). All green, brown, and red seaweeds are protoc-
tists, but so are water molds, slime molds, slime nets, diatoms, ciliates, and many other even more obscure members of this kingdom. The aquatic photosynthesizers—seaweeds, diatoms, golden yellow algae, and the like—differ from the plants, members of the kingdom Plantae, in that, unlike plants, no protist develops from embryos. There is evolutionary continuity between large familiar organisms made of nucleated (eukaryotic) cells and the nucleated free-living single-celled organisms: the protists (this informal term includes all single- and few-celled protists). For over 100 years, and even today, unfortunately, these microorganisms are known as "protozoans." Protozoa, a word derived from Greek roots meaning "first" and "animal," is misleading because "Protozoa" are in no way animals and indeed the early uni- and multi-cellular eukaryotes—the protists—evolved not only into animals but into modern protocists, plants, and fungi as well.

The greatest morphological difference in all of modern life is between prokaryotic organisms—bacteria—and eukaryotes—all the rest of life. From unicellular pond ciliates to blue whales and redwood trees, the eukaryotes show fundamental similarities to each other. At a cell level, the difference between a nucleated amoeba cell and a bacterial cell is far greater than the difference between that of an amoeba, a human epidermal cell, and a sperm cell from the male sex organ of a ginkgo tree. The difference between prokaryotes and eukaryotes is profound: it is comparable to the gap between the Kitty Hawk flying machine of the Wright brothers and the Concorde jet liner. Unlike the evolution of humans from apelike predecessors, which is bridged by the fossil bones of ape–human intermediates (australopiths and Homo species like Australopithecus afarensis, Homo erectus, Homo ergaster, and H. sapiens neanderthalensis), the evolution of eukaryotes from protocysts appears disjoint.

It is almost miraculous that organisms composed of the larger, more complex cells appear in the fossil record. The earliest eukaryotes are fossils known as acritarchs, dated by radioactive igneous intrusives and stratigraphic correlation to be 1,200 million years old. The only evidence for any life prior to the body and trace fossils of extinct, presumed eukaryotes is for bacteria—both as single microfossils and as microbial communities that left fossil remains. Bacterial life is ancient. Evidence for the earliest bacteria places them roughly contemporaneous with Earth's formation of a solid crust, almost four billion years ago. So the big question is: How, from bacteria or protocysts, did eukaryotes, nucleated cells, evolve? The answer seems to be: by symbiosis, or the living together of different kinds of bacteria. The evolutionary process of symbiogenesis—the sequence of events that occur when symbiotic partners merge to form new cells, tissues, organs, or organisms—was crucial in bridging this evolutionary gap. The union of different types of bacteria to form amoebalike cells that became ancestral to the rest of the prokaryotes, fungi, plants, and animals is described here. This event spawned a revolution in biodiversity.

II. DIFFERENCES BETWEEN PROKARYOTES AND EUKARYOTES

One model of the origin of nucleated cells is depicted in Fig. 1. Three distinct symbiotic mergers (blue triangles) are hypothesized.

The first microbes to be discovered were protocysts, today called eukaryotic microorganisms. The pond water microbes studied by Dutch draper turned microscopist Antoni van Leeuwenhoek included Mesodinium rubrum and green algae. Most protocystic cells, evolutionary predecessors to protists, are up to a thousand times smaller than nucleated cells such as those of an amoeba or an animal tissue cell. The term eukaryote literally means "true kernel," from Greek roots; protokaryote comes from words meaning "before kernel." The kernel in question is the nucleus, which contains chromosomes of varying numbers. These numbers are not necessarily correlated to complexity. A dandelion, for example, has many more chromosomes than the forty-six found in all human cells except sperm and egg, which have twenty-three chromosomes each, and blood cells. Mammalian blood cells even lose their nuclei in the process of development and of course eventually die, being unable to reproduce.

As an individual understands the world on the basis of his or her own experience, so have biologists traditionally understood life on the basis of large, familiar organisms. Close inspection of the putative prokaryotic ancestors of all eukaryotes from single-celled yeasts to giant sequoias reveals significant and great differences. Prekaryotes lack true chromosomes. They never have membrane-bounded nuclei. The DNA of bacteria floats free in strands that have little or no protein and often the cells bear DNA in tiny rings called plasmids. Bacterial ("chromonemal") DNA, unlike that of eukaryotes, is not packaged into the winding protein-coated chromosome structures. In eukaryotic cells, DNA complexes with protein and capable of staining a deep red color lines up and separates in an intricate pattern (called mitosis) as the cell divides.
FIGURE 1  Origin of nucleated cells.
Although standard bacteriology texts refer to species of bacteria and assign them binomials (e.g., *Escherichia coli*, *Bacillus anthracis*, *Chromatium pfennigii*), the life-habits of bacteria defy any definition of species, especially the zoological. If a species is defined as a group of organisms whose "members can breed with each other," only one species of bacterium lives on Earth today! In eukaryotes, at least plants and animals, species are maintained by sexual reproduction. Sex cells reminiscent of ancestral protist eukaryotes recognize each other, come together, and fuse to form new cells now with twice the number of chromosomes as the sex cells. These new cells, after fertilization in plants and animals, grow by mitotic cell division (reproduction) to form an embryo. Embryos continue to grow and differentiate into adult plants or tissues and organs of adult animals. Since a bacterium can infect from a few to virtually all of its genes into any other entirely different bacterium, the standard species concept applied to them has no meaning. A bacterium after receipt of genes from another bacterium is a recombinant. This new and different bacterium can then reproduce in its recombined state indefinitely. Sexually-preserved species borders are an imposed fiction in the case of bacteria, because every minute recombination is rampant. Sorin Sonea and Maurice Panisset note that if bacteria had been discovered on Mars instead of on Earth, their astounding natural history would have led scientists to classify them as radically different from all other life-forms.

Other common features of eukaryotes are also lacking in bacteria. Eukaryotes harbor small membrane-bounded bodies called organelles inside their cells. A most important set of eukaryotic organelles, in addition to the ever-present nucleus, are the mitochondria. These are oxygen-using inclusions, respiring entities that provide the cell with energy. All algal and plant cells have another set of organelles that contain chlorophyll: plastids. These are called chloroplasts if they are green. Plastids are named rhodoplasts or phaeoplasts if found inside certain red or brown protoctists (e.g., in coralline red algae or brown kelp). Plastids contain many different pigments, but these always include chlorophyll a, one of the chemical requisites of oxygenic photosynthesis. Chloroplasts mediate the conversion of solar energy into intracellular fuel in algae and plants. They are, of course, absent in animals, whose metabolic fuel is derived from energetic compounds in the environment—food. Another general difference between prokaryotes and eukaryotes is that, with a couple of significant exceptions, eukaryotic cells are aerobes: they depend on oxygen for cell respiration.

The fossil record of oxidized minerals in Earth's crust clearly tells us that free oxygen gas was not present in significant quantities until well after life's origins. Many modern forms of bacteria—such as the methane-generating archaea—coexist with cellulose-degrading bacteria in the special grass-digesting "stomachs" (the rumens) of bison, cows, and water buffaloes—are anaerobes. They are poisoned by oxygen. Today's eukaryotes somehow evolved from earlier life-forms that were intolerant of oxygen. Indeed, modern-day eukaryotes that lack mitochondria, such as pelomyxids, retortamonads, pyrsonymphids, trichomonads, calonymphids, and hypermastigotes, can be interpreted as "living fossils." These swimming protozoa are legacies of the missing links between the tiny gene-trading prokaryotes and the sexual species-forming eukaryotes.

III. SYMBIOSIS AS AN EXPLANATORY MECHANISM

Symbiosis was defined in 1873 by the German botanist Anton de Bary as the "living together of differently named organisms." To the biologist it refers specifically to organisms of different species that remain in more than casual contact. Bacteria of different kinds are certainly recognizable by their morphological and physiological traits rather than by their genetic and sexual behaviors. They need not be confused by inappropriate comparison to the familiar, sexually reproductive plants and animals who can easily be assigned to species proper. Biologists distinguish epibiosis, the symbiotic contact of skin or outer coating, from endosymbiosis, a kind of Jonah-in-the-whale association in which one organism enters, and sometimes fully merges with, the entered organism. Symbiogenesis is a kind of permanent mating. One might be tempted to accuse nature of bestiality were it not for the fact that the "unions" in question far transcend fleeting sexual "mistakes." The Russian naturalist Konstantin Merezhkovsky (1855–1921) was among those of the last century to suggest that symbiosis leads not only to fleeting exploitative (parasitism) or mutually food-providing (symbiotrophic) relationships, but also to the formation of entirely new organs and organisms. He coined the term "symbiogenesis" and described many of the most conspicuous examples. The origin of eukaryotic cells, which represents such a "jump" in both the fossil record and the composition of extant life, is best explained by Merezhkovsky's symbiogenesis. Today, genetic, comparative morphological,
and other lines of evidence suggest that this kind of “innovation by association” was the modus vivendi that transformed gene-trading bacteria into cells with nuclei, mitochondria, and, in the case of algae and plants, plastids. In life’s long history, natural selection acting on symbiogenesis created new species, not only of eukaryotic cells but also of their descendants: sexually reproducing lineages of multicellular bodies. We think that only eukaryotic organisms with their multiple integrated genetic systems form true species.

But how can mere living together lead to the formation of new species? A variety of modern-day organismic associations help to explain this. Epithons, such as the plovers that feed atop crocodiles by cleaning their teeth, are examples of symbiotic partners. They are compensated, if one considers their location and delicious potential edibility, for their services. Episymbiosis often evolves because organisms, which can be viewed as open thermodynamic systems, “leak”—that is, they incompletely make use of food and energy reserves. This leakage allows other organisms to move in. Human skin, even the surface of the human eye and its lashes, serve as a breeding ground for mites and microorganisms. Such normal human accoutrements as bacteria and protists lead to health problems if their populations grow too much. Yet their removal is also dangerous, in part because they keep each other in check. The fungus Candida, for example, which we associate with yeast infections, is normally kept in check by bacteria, which is why yogurt, which contains Acidophilus, is sometimes prescribed as a culinary prophylactic for the ailment.

Endosymbiosis seems disturbingly intrusive, but it leads to radical transformation. An example of endosymbiosis would be the human gut bacteria that metabolize vitamin B12, a vitamin that humans, unaided by symbiosis, would be the human gut bacteria that metabolize vitamin B12, a vitamin that humans, unaided by symbiosis, would be unable to synthesize. A striking example of symbiosis is the seafloor worm, Convoluta roscoffensis, which dwells on the beaches of northern France, southwestern England, and southwest Spain. To the casual observer, this organism is a seaweed: it looks like green scum. During rough seas or stormy weather—or even when a biologist stomps the surrounding ground—the "seaweed" uses its muscles to burrow into the sand. The "seaweed" is really composed of tiny worms whose mouths are closed. They live by direct internal absorption of nutrients provided by the gardens of algae within their cells. The endosymbiotic feeling, as often is the case, is mutual: the host organisms, the worms, receive free nutrients, whereas the resident, eaten but undigested, receive a protective enclosure. The living translucent "greenhouse" of a mobile being results: the green animal eludes environmental danger at a moment’s notice.

Endosymbiosis seems to be a species-creating phenomenon. The freshwater coelenterate Hydra, for example, is transparent, brown, or green, depending on whether its cells contain photosynthetic inclusions full of the green alga Chlorella. Symbiotic associations between other animal hosts abound. Green, food-producing algae or cyanobacteria live inside giant clams, snails, and even in the hair shafts of polar bears. These minute tubes provide a warm, snug locale for Arctic photosynthesizers.

Photosynthetic alliances grow and evolve from relatively casual epibiosis to permanent endosymbiotic mergers. The photosynthesizers that dwell on sun-illuminated surfaces of other living beings are ingested, but in their struggle to resist digestion they continue to metabolize. Their continued metabolism provides the would-be predator with additional food—the evolutionary equivalent of a free lunch.

A somewhat different mode for the establishment of endosymbiosis is that of infection. Microbes in the millions are normally and nonpathologically present on and in plant and animal (including human) bodies. Intimate associations among distinct organisms are not necessarily detrimental. But of course relationships degrade. When one rapid grower enters and exploits another, it naturally produces wastes and may upset a delicate internal balance. Infection can evolve into tolerable truce and permanent productive association if the rapidly growing invader moderates its behavior and growth in response to the "objections" of the would-be invaded.

A striking example of endosymbiosis-by-infection was documented by Korean-American biologist Profesor Kwang Jeon at the University of Tennessee, Knoxville. Jeon’s collection of amoebae were tainted by a sample sent to him by colleagues that contained amoebae infected with bacteria. Most of the new amoebae died. All of the survivors of this natural selection scourgce eventually transformed into what was described as a new species of amoeba. The transformed amoebae retained an internal collection of relatively slow-growing endosymbiotic bacteria. Some 40,000 bacteria resided in each amoeba! Jeon showed that the new amoebae, now an amoeba–bacterial complex, depended on what had once been a fatal infection. To test this hypothesis, he replaced the nuclei from bacteria-containing amoebae with "normal" nuclei from amoebae that were never infected by the newly acquired bacteria. He found that members of the "new" amoeba species invariably died unless they were "rescued" at about three days
postoperative by a reimplantation of the formerly pathogenic bacteria. The nuclei, now accustomed to the presence of hordes of cytoplasmic bacteria, required their continued presence for existence. A chronic deleterious association had become a condition for life; the bacterial "infection" was now an intracellular requirement, and by definition the pathogen had become an organelle.

IV. EUKARYOTE ORIGINS

RNA sequence comparisons of molecules that contain some 1400 nucleotide base pairs sharply divide bacteria into two groups. Professor Carl Woese (at the University of Illinois, Urbana) christened these two groups of organisms—both prokaryotes—"archaebacteria" and "eubacteria." A comparison between Woese's phylogeny that ignores symbiosis and is based on molecular criteria and ours based on symbiogenesis is shown in Fig. 2. Both are of course highly simplified.

As their name suggests, the archaebacteria are putatively a more ancient lineage. Their metabolism appears to have remained relatively unchanged from the early days of an Earth that lacked atmospheric oxygen. The archaebacteria include three great subgroups: methane-producing, thermacidophilic, and salt-tolerant prokaryotes. The first two derive their energy in environments producing, thermacidophilic, and salt-tolerant prokaryobacteria include three great subgroups: methane-producing, thermacidophilic, and salt-tolerant prokaryotes. Both are of course highly simplified.

Both are of course highly simplified.
V. SERIAL ENOSYMBIOSIS THEORY

More than one explanation has been proffered to cover the evolutionary gap from prokaryotes to eukaryotes. Clearly, however, symbiosis—and not just a one-time symbiosis—appears to be involved. All organisms are open thermodynamic systems exchanging matter, energy, and information with their environment. The notion of a totally isolated, independent organism may work as a mathematical assumption or a Platonic idealization, but in the real world of responsive biological activity both genetic exchange and metabolic evolution present untold opportunities for organismic interaction. One organism sheltering another, predator–prey relations, and genetic exchanges lead to alliances of sexuality and symbiosis. Nonetheless, in obeisance to Darwin, traditional evolutionary theory permits only a series of minute and gradual changes that are touted to generate all propagating mutant descendants. Symbiogenesis, the sudden appearance of new organisms by permanent association of different kinds of partners, is not usually what jumps to mind when one considers the evolution of new species. It should.

Serial endosymbiosis theory posits a succession of up to four evolutionary associations that we think led to modern-day cells. The eukaryotic cells of plants are the result of at least two and perhaps three separate evolutionary partnerships among at least three or perhaps four kinds of bacteria. One was the photosynthetic bacteria that conferred photosynthetic abilities upon the ancestors to plants—latter-day cyanobacteria that today exist as the plastid organelles of plant cells. The nucleated cells of animals are the result of at least one, perhaps two separate evolutionary partnerships among at least two or perhaps three kinds of bacteria.

To understand the evolutionary origins of nucleated cells, it helps to return to Earth in its geological infancy. In the Lower Archean eon, about four billion years ago, no protoctists, plants, animals, or fungi existed, only...
the metabolically diverse bacteria. We can provisionally trace the evolution of metabolic diversity by comparison with pathways in modern-day organisms. The first bacteria may have been fermenters because such organisms would need only complex organic compounds preexisting in the environment, rather than other organisms, on which to feed in order to grow. Among the earliest life-forms were photosynthetic cells, green and purple bacteria that much later yielded most of the real estate of the sunlit Earth’s surface to algae and plants. Comparative analyses suggest that these ancient purple bacteria, like their cousins today, used hydrogen sulfide \((H_2S)\) rather than water \((H_2O)\) to make their organic (carbon–hydrogen) bodies. The hydrogen sulfide, spewed from volcanoes, would have been more plentiful on the early, more tectonically active Earth. But as Earth cooled and tectonic activity subsided, sulfide became less available than that ubiquitous solvent water. Mutations appear to have allowed some bacteria to alter the chemical reactions of their metabolism such that they could now, using the energy of sunlight, break the hydrogen–oxygen bonds of water to make their bodies. Life of course existed in water since its inception. But the use of water as a metabolic resource led necessarily to an entropic waste—oxygen. Powered by sunlight, early life discarded oxygen, which reacts strongly with the carbon–hydrogen compounds of living bodies, into the atmosphere. The rock record of rust, oxidized iron, and uranium oxides demonstrates that enormous quantities of oxygen did not begin to build up in Earth’s atmosphere until about two billion years ago. 

Life’s difference from the universe around it, and its tendency to evolve toward greater levels of complexity, reflects its status as an open, entropy-generating system. The use of energy and the inevitable production of waste as a result lead to changes in life as it metabolically stays the same and reproduces. Reproduction of course is an extension of metabolism. But life also changes because of the toxic effects that its growth has on itself. The cyanobacteria that first mutated to use the hydrogen in water for their electron donor were also the first to be poisoned by oxygen toxicity. Among the prolific anaerobic organisms living at the surface were also rapidly swimming bacteria including spirochetes, many kinds of which dwell today in symbiotic alliance with other organisms in the hindguts (swollen inenterines) of wood-eating termites. Just as the Industrial Revolution changed human civilization in part due to new systems of railway, steamboat, and eventually airplane transportation, fast-moving bacteria are posited in Serial Endosymbiotic Theory (SET) to have conferred major changes upon early cells.

The most provisional part of the evolutionary story of the symbiotic eubacterial origin of eukaryotic cells is the part that explains the origin of intracellular movement. The association of fast-moving eubacteria, perhaps spirochetes (speedy corkscrew-shaped burrowing feeders upon and even permanently attached to other organisms), with larger archaeabacteria is postulated to be the most far-reaching but integral part of the story. Intracellular mobility—the “cytoskeletal system”—of all eukaryotic cells is remarkable for its extent, complexity, and ubiquity. Cells with nuclei not only undergo the elaborate alignment and separation of reproduced chromosomes during mitotic cell division, they also have characteristic motility structures such as the mitotic spindle with its microtubules. Microtubules, 24 nm in diameter and varying in length, are not found in prokaryotes. Among the many microtubule-based structures such as sperm tails, cilia, and moving spines are the mitotic spindles themselves. The mitotic spindle, crucial for eukaryotic cell reproduction, seems to appear out of nothing to become superbly organized and to separate chromosomes during cell division. Eukaryotic cells are famous for the incessant streaming of their cytoplasm. The intracellular activities are reminiscent of a crowded train station filmed in time-lapse photography. Many kinds of nucleated cells (of plant sperm, animal tissue, and myriad protists) bear special motility structures that display a ninefold symmetry in cross section. These, whether cilia, sperm tail, or sensory hair, are called “undulipodia.” The whipping tail used in cell propulsion, sensory detection, or propulsion of eggs along the fallopian tubes of mammals are all examples of undulipodia. In cross section the shafts of these motile cell structures have a characteristic “\(9(2)+2\)“ pattern. As seen with the electron microscope, nine pairs of tubes surround one central pair. This cross section structure, 230 nm in diameter, is found to be nearly universal in eukaryotic organisms, from the whipping tails of the sperm of ferns, mosses, cycads, and trees (yes, some trees do produce sperm) to the cilia that propel gastropod and insect cilia. In all prokaryotes whether archaeabacteria or eubacteria, undulipodia are the most far-reaching but integral part of the evolutionary story of the symbiotic eubacterial origin of eukaryotic cells. As has often been witnessed in modern-day symbiotic partnerships, the rapid swimmer would have been attracted to the food leaking out of the larger
bacterium and the partnership would eventually have been selected in the evolution of permanent motile associations. Ciliates today often differ only in the placement of their undulipodia. Moreover, the microsurgical grafting of patterned patches of undulipodia from one ciliate to another leads to altered patterns in which the ciliate reproduces without benefit of a sexual partner. Although DNA is absent in the motility organelle of waving undulipodia itself, many other facts suggest a possible symbiotic origin. Grafted patterns of altered undulipodia “breed true.” The sheer resemblance of whipping undulipodia—not easily differentiable in some organisms, such as Mixotricha paradoxus, from actual attached spirochetes—to fast-moving, free-living bacteria provides a clue.

Early evolution may have featured a great proliferation of mastigote (undulipodiated) cells resulting from a successful union of anaerobic archaebacteria and spirochetes or spirochete-like organisms in which the DNA of the motile form entered the newly evolved nucleus as it formed. The quick-swimming partnership complex would have conferred a greater ability to acquire food on the merger. The greater access to new food by the larger, more quickly moving moving archaebacterial–eubacterial complex portended a great future. As often occurs in evolution, association led to new opportunity and power. Eventually, the greatest, most integrated partnerships formed unified genetic entities. These genetic entities went on to add new members in the evolution of new cells, protocist lineages ancestral to plants, fungi, and animals.

Much more and better-quality evidence exists for later symbioses. Whether or not swimming eubacteria merged with archaebacteria to form mastigotes such as ciliates, these undulipodiated cells were very likely invaded or infected, some two billion years ago, by oxygen-using bacteria. These oxygen-using or respiring bacteria, similar to free-living forms today—some of which are not only oxygen-respiring but also invaders of other cells (e.g., Bdellovibrio)—proliferated in the aftermath of the evolution of oxygenic photosynthesis. The gaseous waste from using water as a source for hydrogen was the production, eventually at a planetary level, of the highly reactive oxygen gas (O2). This gas naturally, and sometimes fatally, burns cell tissue. Many organisms were forced to retreat to the muds, out of harm’s way. Some hung on until animals such as the ancestors to insects evolved. Hiding like soldiers in a tank or submarine, the oxygen-poisoned anaerobes today prolifere only in biological enclosures, such as sulfurous muds, the termite hindgut, the cow rumen, or other natural protective settings. The respirers, however, turned the metabolic negative of volatile oxygen into the metabolic positive of a new, more efficient source of energy. Bulging about, funneling potentially dangerous redox reaction into their own growth, the ancestors to mitochondria kept the harmful gas away from others by using it themselves. This quality led to the greatest burst of biodiversity of all: the fabulous protocist proliferation of respirers, both alone and in associations with other organisms. The symbiotically evolved amoeba of Jeon, mentioned earlier, were infected with respirers. Merged with mitochondriate, anaerobic mastigotes, the respiring forerunners to modern mitochondria powered the metabolism of the cells of all the major macroscopic lineages: protocists, fungi, plants, and animals.

The final major symbioses—for which, as in the case of mitochondria, there is good genetic evidence—occurred in the ancestors to algae and plants. Taxonomically, the major difference between algae and plants is that plants form from a fertilized nucleus that grows into an embryo that is retained in maternal tissue. By definition the embryo is a multicellular eukaryote that develops from a fertilization event, the fusion of two nuclei from complementarily gendered parents. Algal growth is more beltier-skeleton, amorphous, and never embryonic. The archaebacteria, perhaps with symbiotic spirochete offspring providing them varied means of mobility, merged with respiring bacteria. Today mitochondria, although they cannot be grown on their own, appear sometimes to revert back to their earlier, freely reproducing lifestyle; in cancer cells, for example, mitochondria reproduce rampantly. The nucleus itself does not appear to be the direct result of cell symbioses. The nucleus may, however, represent the intracellular equivalent of a “government” that evolved to deal with the first merger of separate cell lineages shown as the lowest triangle in Fig. 1. After the original archaebacterium–mitochondria module was established, the new nucleated cells had to feed. Many fed on photosynthetic bacteria. Bacteria do not have immune systems, and “eaten” food, like Jonah in the whale, continued to live and sometimes even reproduced. Although perhaps highly perilous, for starving mastigotes with symbiotically derived mitochondria it might also have been a godsend. With all the competition to find food, those who produced their own, or merged with photosynthetic organisms capable of production of their own food, would have been at a distinct advantage under the usual conditions of starvation. The algae and its derivative plant lineage are traceable to eukaryotes that symbiotically acquired bacterial photosynthesizers.
Today all familiar visible organisms are eukaryotes with nucleated, mitochondriate cells. Whether at the zoo, the forest, or the green prairie, we witness not isolated individuals but an evolutionary fact of life: hundreds of millions of years of symbiotic interliving. The simplest amoeba is no independent cell, rather it represents the outcome of an evolutionary flirtation with death and microbial diversity. A large animal, such as a hedgehog or woman, is a highly organized, differentiated clone of amoeba-like protist cells. An overall classification of life based on this view of the symbiogenetic origin of eukaryotes is shown in Fig. 3. Biodiversity is obvious, widespread, and crucial to our global environment. The existing major phyla, classes, genera, and species resulted not only from mutation accumulation but also by symbiotic alliance and permanent merger. Microbial proliferation and diversification behind the production of new species and large evolutionary transi-
EUKARYOTES, ORIGIN OF

Eukaryotes, the cells with a clearly defined nucleus and organelles, are the origin of complex life on Earth. The processes in the past are still with us as the understory of life on Earth.

I. Introduction
II. Ecosystem Diversity: Concepts and Approaches
III. Biodiversity of Habitats and Vegetation
IV. Challenges for the Future

GLOSSARY

biome A large-scale complex of ecosystems sharing similar climate and vegetation structure.
ecological biodiversity Variety of biotic communities (plant, animal, and microbial communities) and their complexes (ecosystems, landscapes, and biomes).
formation Large-scale (subcontinental or continental) vegetation complex defined primarily on the basis of a combination of dominating life-forms (hence, vegetation structure).
habitat A place of dwelling of a biotic community (or a complex thereof) showing particular combination of ecological factors occupying certain area in a certain period of time.
oroborne Mountain range characterized by particular climatic pattern and characteristic sequence of vegetation zones.
syntaxon (plural syntaxa) A category of vegetation typology based on the floristic-sociological approach (known also as the Braun-Blanquet approach); the basic syntaxon rank is “association,” which further groups into “alliances,” which group into “orders,” and orders group into “classes.”
vegetation megazone Large-scale vegetation complex characteristic for a zonobiome.
vegetation survey Product of research activity aimed at the description and classification of vegetation cover on various levels of complexity in a certain geographic area using various field and data-evaluation methods.
zonobiome Broad ecological topographical unit characterized by a certain climatic pattern.

THE PROBLEM OF biodiversity of European ecosystems is approached from the point of view of biomes and zonobiomes, flora-based vegetation typology (phytosociological tradition to classification of vegetation), and habitat classifications. The concepts of biome (based on a combination of dominating life-form and climate) and zonobiomes (by H. Walter) are compared for Europe. The most effective classification of ecosystems in Europe is based on the floristic-sociological approach, which has deep roots in European tradition and is widely used throughout Europe. This approach has yielded a hierarchical system of vegetation units which allow insight into the diversity of vegetation types of this continent. Basic features of diversity of vegetation types (syntaxa) are briefly outlined, and the importance of vegetation classification for delimitation...
and calibration of habitat classification systems in Europe is discussed. The tasks for further research and socioeconomic implications of the diversity of ecosystems in Europe are outlined.

I. INTRODUCTION

Hardly any place in the world supports in a relatively small area such a variety of countries, peoples, cultures, histories, languages, political views, cuisine, and types of cheese and wine as does Europe. There might be more languages and people in India, higher species diversity of plants in the tropical rain forest of Columbia, or more diverse cuisine in China, but there is only one Europe.

Europe's nature is showing many faces, both pristine ones in the form of tracks of tundra and forests and created (or mis-created) ones—those carrying the signs of the hand of man. Europe is a patchwork of ecosystems connected by an intricate net of gradients of ecological factors ranging from those controlling continental patterns of vegetation megazones and biomes to local gradients creating small-scale mosaics of biotic communities.

This article discusses the variability of European ecosystems and a major framework of biodiversity patterns at various scales of complexity.

Europe is a continent, a large chunk of land; therefore, I discuss this subject from the viewpoint of diversity of large-scale ecological units such as vegetation megazones and biomes. The terrestrial habitats (and their complexes) will dominate this discourse and I emphasize the diversity of vegetation assemblages, which are traditionally considered the core of structure and functioning of all terrestrial ecosystems.

Europe is approximately 10 million km$^2$ and spans 35–81°N of latitude and 60°E–10°W of longitude. Although Europe is the second smallest continent (7% of the world's land surface), the basic classification of ecosystem diversity can be discussed only at a very large scale of biome. Not only the limited extent of this article but also the extraordinary wealth of scientific knowledge collected over centuries and the diversity of the subject impose constraints on the level of detail and accuracy of this discourse.

II. ECOSYSTEM DIVERSITY: CONCEPTS AND APPROACHES

Ecosystem, often defined as the union of biotic community and its environment, presents an obvious difficult scaling problem. Ecosystems as real entities occur in space and time. Depending on conditions, one can recognize natural or artificial borders allowing classification of ecosystems, an exercise meant to set a framework for simplifying the complexity of ecosystems and featuring them in a synoptic way.

A. Classification of Vegetation

Most European ecosystems are obviously terrestrial ecosystems accompanied by semiterrestrial and aquatic ones. Vegetation (defined as the unity of plants occupying certain area in a certain time, Palmer and White, 1994) is the major biotic element of terrestrial ecosystems. Hence, the problem of classifying terrestrial ecosystems is a problem of classification of vegetation.

The approaches to the classification of vegetation are manifold and largely depend on criteria (and their weighting), aims, and means (Mucina, 1997a). Several basic approaches to classification of vegetation have emerged during the past century (Whittaker, 1978). Among these, the floristic–sociologic approach (Westhoff and van der Maarel, 1978; Dierschke, 1994) became a standard communication tool among European (and other) vegetation scientists involved in or harvesting fruits of vegetation classification exercises.

1. Floristic–Sociologic Approach to Vegetation Classification

The basis of the floristic–sociologic approach to classification of vegetation is the notion of the total floristic composition and the notion that some species indicate the environmental conditions better than others. These are called diagnostic species (Braun-Blanquet, 1964). Vegetation stands are selected by following various criteria, among which the so-called representativity of the studied vegetation type is the leading one. This approach is aimed at recognition of plant communities—plant assemblies recurrent in space and in time and showing distinct floristic composition which reflects certain combinations of current and past habitat conditions. The basic vegetation unit of this approach is the so-called association, a theoretical construction that is a result of the abstraction classification process involving many vegetation stands. A hierarchy of vegetation units based on groups of species having similarity between plant communities and their groups is also a vital part of the floristic–sociologic approach. Floristically and ecologically similar associations are grouped into alliances, the alliances are grouped into orders, and the orders are grouped into classes. The vegetation classes can be less formally grouped into divisions. Particular
associations, alliances, orders, classes, and divisions are termed syntaxa (Westhoff and van der Maarel, 1978) of various ranks and build the syntaxonomic hierarchy. An elaborate, highly formalized system of rules has been introduced to govern the formation of names of the syntaxa.

2. Dominance Approach to Classification of Vegetation

Another approach to classification of vegetation emphasizes the role of the dominant species or dominant growth forms, marking a departure from using plant taxonomy as the currency. Without discussing this approach in great detail (Whittaker, 1978), the notion of formation is the core tool of the dominance approach. The formation is the vegetation component (thus, in terrestrial ecosystems it is the leading element) of the concept of biome. Although the floristic–sociological approach is well suited for classification and description of vegetation on small geographic scales, formation and biome are, for the same purpose, well suited on large scales (subcontinental and continental).

3. Classification of Habitats

Despite much critical challenging of some subjective points regarding criteria for selection of stands and criteria of weighting of species in the classification process and sometimes awkward nomenclature, the floristic–sociological approach is aimed at enhancing effectiveness of communication when addressing units of vegetation cover. It is therefore not surprising that it was the terminology and concepts of this approach that were adopted as the basis of the majority of the units of the habitat systems developed for various purposes by the former European Communities (now European Union) authorities.

The classification of habitats passed several stages of development, spanning CORINE habitat classification (Commission of European Communities, 1991), Palearctic habitat classification (Devillers and Devillers-Terschuren, 1996), and EUNIS habitat classification (Davies and Moss, 1998). Obviously, the purpose of habitat classification is a practical one. It should serve (and serves) important purposes by delimitation and evaluation of land-use characteristics, projection and management of nature reserves of other areas of special nature conservancy interests (e.g., the Natura 2000 network of Special Areas of Conservation), etc. Not surprisingly, such a habitat classification scheme is a legal standard within the borders of the European Union.

III. BIODIVERSITY OF HABITATS AND VEGETATION

A. Sources

The current vegetation landscape of Europe is a result of manifold forces forming and reforming the habitat networks during the past few thousands of years; undoubtedly, some features of this habitat and vegetation patchwork are very old.

One can hardly avoid using oversimplification when talking about the sources of community (including vegetation and animal communities) and ecosystem diversity of present-day Europe. I distinguish four major prerequisites to the community and ecosystem diversity (Table I):

1. Taxon diversity: Plant and animal communities are composed of individuals belonging to several (often many) taxa. Speciation and associated processes of within-taxon diversification in addition to migrations of taxa—either ancient, natural ones or current ones largely driven by man’s activities—are the major sources of taxon diversity.

2. Habitat diversity: Habitats are “homes” of biotic communities and the greater the variety of habitats, the greater the variety of biotic communities populating them. The character of habitats is determined primarily by ecological factors—their character and dynamics. Regardless of whether one considers spatial or temporal scales, one can recognize geological, geomorphologic,
and soil-formation processes accompanied by hydrological dynamics and climate changes as the major natural sources of the habitat diversity.

3. Diversity of biotic interactions: The individuals representing different taxa interact within the biotic communities in many ways. They may compete for resources, facilitate each other's growth and reproduction by a plethora of positive interactions, and may behave indifferently. Undoubtedly, the biotic interactions form the face of each community and thus contribute to ecological diversity.

4. Diversity of human interference: Man has made himself the center of the universe and from this point of view has also become the dominant source of the disturbance (up to complete removal) but also creation of new habitats and new biotic communities through manipulating ecological factors and facilitation of species migrations.

B. Patterns

1. Biomes of Europe

Europe has six (of the world's nine) zonobiomes as defined by Heinrich Walter (Walter and Breckle, 1991, pp. 22–25). These include, from south to north, Mediterranean zonobiome (IV), warm-temperate zonobiome (V), nemoral zonobiome (VI), continental zonobiome (VII), boreal zonobiome (VIII), and polar zonobiome (IX). Furthermore, many zonoecotones mediate between the particular zonobiomes and those are designated as IV–V, V–VI, VI–VII, VII–VII, VII–VIII, VIII–VII, VIII–VI, and IX–VIII. The zonoecotone III–IV, mediating between subtropical zonobiome (not represented on the continent) and Mediterranean zonobiome, is found on the Canary Islands.

The Walter's biome scheme, largely based on a combination of climatic characters, is currently under revision in light of more modern definitions of the biome concept involving the combination of climate and functional types (including traditional life-forms) using modeling to predict vegetation patterns (Prentice et al., 1992; Haxeltine and Prentice, 1996) or to reconstruct the patterns of the past (Prentice et al., 1996).

Following the combined approach to define biomes using climate and vegetation structure, one can tentatively recognize 10 biomes in Europe and the Canary Islands (Table II).

Surprisingly little attention has been devoted to the definition of extant European biomes in comparison with other parts of the world. This can to a great extent be attributed to traditions in classification of ecosystems in Europe. The dominance-based approach to classification of vegetation leading directly to definition of biomes when exercised on a large scale is the predominant approach in parts of the world in which there is a lack of advanced knowledge on flora. Europe is undoubtedly a region in which the flora-based approach has a long and firmly rooted tradition.

2. Diversity of Vegetation Types

To list all syntaxa described in Europe is impossible here. Recent account of the high-rank syntaxa (Mucina, 1997b; Rodwell et al., 1998) revealed that the European vegetation can be classified into 75 classes (Table III).

The definition of Europe includes Europe proper, Iceland, Madeira, Azores, and the Canary Islands. For a full nomenclature, major species groups, and literature sources, see Mucina (1997a). Or, number of phytosociological orders; Al, number of phytosociological alliances. Biomes and orobiomes: T, Tundra Biome; B, Boreal Evergreen Forest Biome; N, Temperate Deciduous Forest Biome; M, Mediterranean Biome; CSD, Continental Semidesert Biome; SSD, Subtropical Semidesert Biome; S, Temperate Grassland (Steppe) Biome; L, Temperate Laurisilva Forest Biome; R, Temperate Rain Forest Biome; OA, Alpine Orobiome; OM, Mediterranean Orobiome. The abbreviations in parentheses indicate “in part” statements.

provides the major features of these classes), 223 orders, and 844 alliances. The number of associations is unknown, although one estimate suggests there might be as many as 2300–3000. For further details on the diversity of syntaxa occurring in various European countries, refer to the many national vegetation surveys (and transnational vegetation accounts) listed in Table IV.

Several interesting biodiversity patterns can be observed within the groups of syntaxa, including classes, orders, and alliances (Table III):

1. The Mediterranean region (supporting the Mediterranean biome and Mediterranean orobiome) shows a high concentration of classes and subordinated syntaxa. This can be partly ascribed to high alpha, beta, and gamma diversities (Cowling et al., 1996) and partly to the insular character of many types of Mediterranean habitats (and their complexes). Not only are numerous true marine islands very abundant within the Mediterranean basin but also the mountain summits form an archipelago of their own, demonstrating their own rates of evolution and combination of ecological and biogeographical factors leading to specific plant assemblages.

2. The high-latitude regions (arctic and boreal zones) show lower diversity of vegetation types partly as a result of low extant alpha diversity that diminished dramatically by the last ice age, partly because of the large-scale occurrence of uniform habitat complexes, and partly due to adversity of climate.

3. A group of azonal (and intrazonal) rather than broadly distributed zonal classes shows the highest diversity of orders and alliances (reflecting high diversity of ecological–biogeographic patterns). Among those with a particular position are Asplenietea trichomanis and Thlaspietea rotundifoli (classes comprising vegetation of special habitats such as rock faces, fissures, and screes), on the one hand, and classes of Festuco-Brometea, Koelerio-Corynephoretea, and Puccinellio-Salicornietea (comprising both primary and secondary dry grasslands, on the other hand. The former two classes have insular character of distribution pattern: The communities are small scale, occupying ecologically isolated habitats and housing most European endemic species. The group of dry grassland classes have relatively large-scale distribution and comprise Europe’s most species-rich plant communities. Russian steppes, for instance, can support more than 60 species per square meter. Large-scale distribution and rich species pools are prerequisites to high beta diversities manifested in a high number of vegetation types.

4. The synanthropic (man-made and man-controlled) vegetation of Europe is also very diverse in terms of the number of syntaxa. The classes of Festuco-Brometea, Koelerio-Corynephoretea, and Puccinellio-Salicornietea (comprising both primary and secondary dry grasslands) on the other hand. The former two classes have insular character of distribution pattern: The communities are small scale, occupying ecologically isolated habitats and housing most European endemic species. The group of dry grassland classes have relatively large-scale distribution and comprise Europe’s most species-rich plant communities. Russian steppes, for instance, can support more than 60 species per square meter. Large-scale distribution and rich species pools are prerequisites to high beta diversities manifested in a high number of vegetation types.

5. Mediterranean classes such as Thero-Brachypodietea, Rosmarinetea officinalis, Quercetea ilicis, and, to some extent, Cisto-Micromeretea also show high diversity with regard to the number of alliances. Still

#### *A bibliography of the featured surveys and checklists can be requested from the author.*

1 M, single monographic treatment; SM, series of monographic treatments; R, report serving a government body; C, conspectus (short account of vegetation units including limited descriptive treatment); L, list of vegetation units.
higher diversity becomes obvious on the level of associations reflecting the relict character and diversity of disturbance regimes showing a fine-grain pattern in the Mediterranean.

6. The lowest diversity of vegetation types is encountered in the classes typifying vegetation of the freshwater, marine, and coastal vegetation. Often, only a few orders or alliances are found within classes such as Lemnetae minor, Potametea, Spartinetea, Hockenyo-Elymetea, and Crithmo-Staticetea. However, on the whole, the nonterrestrial complex of habitats is very diverse, which is reflected in the high number of phytosociological classes.

3. Diversity of Habitat Types

Although vegetation forms, at least in the terrestrial ecosystems, the major component of these ecosystems, the habitat typology cannot reflect and is not reflecting only vegetation typology. For instance, as found by Rodwell et al. (1998), 60% of 277 units of the EUNIS3 habitat classification were characterized in phytosociological (syntaxonomic) terms, whereas the other units are largely abiotic and carry geomorphologic and hydrological features or they are associated with fauna or nonvascular plants. Table V shows that this is the case especially in EUNIS habitat classes (groups of similar habitats) such as class A (marine habitats) and class J (constructed, industrial and other artificial habitats).

The judgment on diversity of habitats appears more difficult than that based on classification of vegetation. First, there are many incommensurable variables to be considered by definition of a habitat type. Second, the spatial and temporal scaling of the habitat types

is very complex. This complexity is reflected in all classification systems of habitats known until today. In order to cope with the complexity, the habitat classification systems are hierarchical, but often on the same level of hierarchy, thus mixing small-scale habitats with habitat complexes recognizable on the landscape level. Obviously, the calibration of the habitat units and the classification system leaves much room for improvement (Rodwell et al., 1998; Waterton et al., 1998).
IV. CHALLENGES FOR THE FUTURE

There are many perspectives on ecological diversity. I present one that is not the favorite of granting agencies in Europe (and perhaps also elsewhere): the perspective of the diversity of ecosystem types themselves.

The legitimate status of the concept of ecological diversity as a virtual part of biodiversity has been recognized since “biodiversity,” a brushed-up concept, started to sweep research agendas throughout the world. This happened largely due to the catalyzing effect of the U.S. Strategy Conference on Biological Diversity (Ghilarov, 1996) and later “beatification” of biodiversity by the Rio World Summit and resulting documents of the convention. Ecological diversity (including diversity of communities, ecosystems, landscapes, and biomes) was recognized by international and national bodies as a subject worth studying (and supporting) in the name of developing technological tools for its protection and sustainable use.

In Europe, as elsewhere, taxonomic diversity is the leading topic of biodiversity research and conservation. However, due to deeply rooted research traditions and the awareness of national governments, surveys on higher levels of biological complexity have been given much attention in the past. Almost every European nation has a national vegetation map, and many have land-use and landscape-unit maps. Modern national vegetation surveys have been recently completed or are under way in many crucial European countries. [see Table IV for a survey; see Mucina et al. (1994) and Rodwell et al. (1993) for progress reports].

With Europe growing together as a union of nations sharing political agendas and an economic future, the large-scale tools for ecological diversity conservation and sustainable use are emerging. These include pan-European habitat classification scheme EUNIS, a vegetation map of Europe (a long-term cooperative project headed by Dr. U. Bohn, Bonn, Germany), and the European Vegetation Survey (a Working Group of the International Association for Vegetation Science). The fall of the Iron Curtain in 1989 and 1990 posed a new challenge for research agendas in ecological diversity—unification of scientific standards and application tools along the West–East gradient within Europe. There is still much progress to be made.

Also, because we need to know the flora and fauna (as well as their intraecosystem variability down to the genetic structures), we need to survey biotic communities, habitats, ecosystems, and biomes. This need is not only fed by scientific curiosity but also by practical, technological needs to ensure effective conservation and use of biological diversity as a whole.

Acknowledgments
I am indebted to Milam Chitty, Harriet Dutschke, Julian Dring, Sandro Pignatti, John Rodwell, and Joop Schaminee for long and fruitful discussions on the diversity of European vegetation—our common passion. Roberto Camillo carefully read the penultimate manuscript version.

I. Introduction
II. Changes in Flora and Fauna
III. Oligotrophication: Reversing the Impacts of Eutrophication

GLOSSARY

algae Primitive plantlike organisms that photosynthesize. These organisms can be unicellular, filamentous, or colonial microscopic forms (microalgae), or they can be macroscopic (macroalgae), consisting of a primitive plant body (thallus) that lacks vascular tissue in most species.
anoxia Condition in which there is almost no dissolved oxygen in the water (<0.1 mg of dissolved oxygen (DO)/L).
bloom Proliferation of algae in river, lake, estuarine, or marine waters. Older literature referred to a bloom as 3000 or more algal cells per liter (L) (or 5 cells per ml), although this density generally is too low to discolor the water. Algal 'blooms' range in cell density from eukaryote blooms (e.g., dinoflagellates at $10^3$ to $10^4$ cells/ml, to cyanobacteria at $10^8$ to $10^9$ cells/ml).
eutrophic Trophic status of an aquatic ecosystem that is characterized by relatively low phytoplankton species diversity but high phytoplankton production (biomass as mean chlorophyll a ca. 15–40 μg/L), with the phytoplankton often dominated by cyanobacteria in lakes, and by dinoflagellates or other flagellates in estuaries; high nutrient concentrations and loadings (for example, in lakes, mean inorganic N ca. 1900 μg/L, mean total P ca. 80 μg/L), high decomposition in the bottom water and surface sediments (with abundant organic materials available for this process); and bottom-water dissolved oxygen deficits, sometimes with occasional to frequent fish kills. Eutrophic lakes typically are shallow with well-developed littoral zones (area where light penetration is sufficient to support growth of rooted plants), sometimes extending across most of the bottom area.
harmful algae Algae that are undesirable to humans because (a) they become too abundant in response to nutrient overenrichment and then, at night, use most or all of the oxygen in the water for their respiration, so that fish and other organisms suffocate or become seriously physiologically stressed; (b) they become too abundant in response to nutrient enrichment, and overgrow beds of desirable rooted vegetation so that the beneficial plants cannot receive enough light to survive; (c) they cause or promote disease in other plants or animals, or (d) they produce toxins that hurt or kill finfish, shellfish, or other higher trophic levels including humans. "Harmful algae" include prokaryotic cyanobacteria or blue-green algae. More recently, the term has been used to include organisms that are not photosynthetic, primitive plantlike organisms—for example, certain nontoxic animal-like dinoflagellates, which cause fish disease (e.g., Amyloodinium ocellatum), and toxic animal-like dinoflagellates (e.g., the toxic Pfiesteria complex), which do not have their own chloroplasts
mesotrophic
Trophic status of an aquatic ecosystem that is characterized by moderate phytoplankton production and moderate nutrient concentrations and loadings.

mixotrophy
Form of nutrition involving both autotrophic (photosynthetic) and heterotrophic carbon acquisition.

oligotrophic
Trophic status of an aquatic ecosystem that is characterized by relatively high phytoplankton species diversity but low phytoplankton production (chlorophyll $a \leq 10 \mu g/L$); low nutrient concentrations and loadings (for example, mean inorganic N $< 200 \mu g/L$, mean total P $< 10 \mu g/L$); low decomposition (with little organic material available to decompose); and plentiful oxygen throughout the water column.

salt wedge
Water from the ocean, with higher salt content, that moves into an estuary along the bottom of the water column, beneath less dense fresh water that has moved into the same area from a river. The salt content makes the ocean water heavier than the fresh (riverine) water, so that under calm conditions, the estuarine water becomes density-stratified. This “salt wedge” of bottom water can become somewhat isolated from the overlying fresh or less brackish water. The longer the period in which the total water column is not mixed by winds or storms, the more distinct the two water layers or strata become. Salt wedges most often develop in warm seasons when plantlike phytoplankton production is high in the surface waters and respiration by heterotrophs (bacteria, fungi, animals) is also high, especially in the lower water column and sediments. Nutrients typically are higher within the salt wedge than in the overlying water, because of decomposition processes. At the same time, the bottom-water salt wedge can become hypoxic or anoxic, underlying waters can be saturated or supersaturated with oxygen from phytoplankton photosynthesis.

trophic status
Ranking system for aquatic ecosystems, based on the amount of organic production and nutrient (N,P) levels. The major component that is usually considered in assigning trophic status is phytoplankton production, but this can be misleading. For example, some lakes are classified as oligotrophic because water-column nutrients and phytoplankton production are low, despite the fact that benthic plant production (e.g., of rooted angiosperms) is high.

EUTROPHICATION IS the natural aging process of aquatic ecosystems, formerly used mostly in reference to the natural aging of lakes wherein a large, deep, nutrient-poor lake eventually becomes more nutrient-rich, more productive with plant and animal life, and slowly fills in to become a pond, then a marsh. More recently, this term has been used in abbreviated reference to “cultural” or accelerated eutrophication of lakes, rivers, estuaries, and coastal marine environments, wherein the natural eutrophication process is accelerated (often by hundreds or thousands of years) by human activities that add nutrients to the aquatic system. Oligotrophication is a reversal of the eutrophication process, in which waters become less nutrient-enriched and/or support less plant and animal production. This process can occur naturally, for example, when the inflow to a moderately productive lake is severed so that the lake slowly becomes an ombrotrophic, nutrient-poor system or bog. Oligotrophication can also occur from human intervention, for example, following diversion of sewage from a small lake and dredging/ removal of nutrient-rich bottom sediments.

### I. INTRODUCTION

#### A. Overview across Aquatic Habitats

From freshwater lakes to estuaries and marine coastal waters, human-derived sources of nutrient pollution have rapidly changed water quality and aquatic community structure within the past 200 years of industrialization and rapid population growth. The predominant theme throughout most of the world is increased nutrient enrichment or cultural eutrophication, rather than nutrient decreases or oligotrophication; thus, eutrophication will be emphasized here although both phenomena will be addressed. Despite advances in treatment of human sewage in some countries during the late 20th century, despite bans on use of phosphorous in certain domestic or industrial practices, despite declines in agricultural fertilizers in some geographic regions,
EUTROPHICATION AND Oligotrophication

and despite modest improvements in environmental education in localized areas, the massive recent increase in global human population growth has increased nutrient loadings to aquatic ecosystems (Fig. 1). These increases have been greatest in estuarine and coastal marine areas where population growth has been highest, and where nearly two-thirds of the people of the world now reside. As a reflection of this trend, estuaries have been reported to receive more nutrient inputs per unit surface area than any other type of aquatic ecosystem. Nutrients are essential for primary production by phytoplankton, benthic micro- and macroalgae, and aquatic angiosperms, which directly or indirectly support aquatic food webs. In freshwaters, phosphorus is the least abundant among the nutrients needed in large quantity (macronutrients) by biological organisms. Thus, it is the first element that becomes limiting to biological productivity in many freshwater systems. Phosphorus is also the nutrient that limits plant growth in many tropical coastal marine waters. In temperate and polar coastal marine environments, nitrogen is the most important nutrient that first limits primary production; and at the estuarine interface between marine and freshwater habitats, both N and P can "colimit" plant production, especially in late winter-spring seasons of high precipitation and accompanying high inorganic N inputs. Other nutrients, notably silica and iron, can also sometimes significantly influence the outcome of species dominance and the structure and abundance of phytoplankton communities under cultural eutrophication.

In moderation, nutrients promote beneficial increases in phytoplankton and benthic algal production and, in turn, higher production of zooplankton, macroinvertebrates, fish, and shellfish that utilize the plant production directly or indirectly for food. But when added in excess, nutrient pollution can cause overgrowth of macro- and macroalgae, leading to oxygen depletion in bottom waters and sometimes throughout the water column. Although fish kills can be an obvious sign of acute impacts from cultural eutrophication, associated subtle, chronic impacts may be more damaging to aquatic communities over the long term. Sustained loss in biodiversity is foremost among these chronic impacts, resulting from underlying mechanisms that scientists are only beginning to understand.

Cultural eutrophication promotes major shifts in the structure of both plant and animal communities, generally affecting dominant components of every trophic level from microbial decomposers to macrofauna. There is clear, compelling evidence of altered aquatic community structure and significantly reduced biodiversity from cultural eutrophication in many freshwater, estuarine, and marine ecosystems. Surface waters across the earth are now sustaining such impacts; even the open oceans are no longer sufficiently isolated to avoid nutrient pollution from atmospheric deposition. Similar trends have been demonstrated from the microfossil records of lakes and of estuaries, showing a dramatic increase in nutrients and associated organic carbon deposits and a sharp, sustained decrease in the diversity of aquatic species.

B. Factors Influencing Impacts from Nutrient Enrichment

Among the most important factors that influence the extent of adverse impacts from nutrient enrichment is water exchange rate, or the time required to completely replace the water in the system with new water. Waters that can “self-cleanse” or rapidly flush, such as fast-flowing rivers or run-of-river impoundments, are less sensitive to elevated nutrient loading than more contained or enclosed waters such as lakes and estuarine lagoons. Similarly, waters along open, wave-swept marine coasts are less sensitive to nutrient loading than quiet, sheltered upper embayments. The occurrence of other pollutants along with the nutrients—for example, suspended solids that can reduce light for growth of aquatic plants or toxic substances and harmful bacteria that can stress or kill some aquatic species—can exacerbate impacts from nutrient enrichment. The form of the nutrients can also be important. For example, swine wastes are much richer than untreated human sewage in organic nutrients (N, P, and C). Certain undesirable algae prefer organic nutrient forms over inorganic sources.

The timing and frequency of the source inputs are important, as well. During high-precipitation periods in winter, sewage is more effectively diluted and cold temperatures discourage the growth of many nuisance algae. Also, in some waterways, agriculture is the major source of nutrients annually, but during low-flow periods in warmer seasons, sewage can contribute half or more of the river volume and the loading of nutrients—at a time when the readily available nutrients stimulate noxious algal overgrowth of the system.

The initial aquatic community structure also influences the overall impacts of nutrient loads to aquatic ecosystems. Systems with low nutrient enrichment rely more on recycled nutrients than on introduction of new nutrient sources, and this may be a driving evolutionary force leading to greater specialization and diversity, as suggested by Howarth and others. Diverse communities, characteristic of oligotrophic or nutrient-depauperate waters, tend to be dominated by sensitive species that are limited to a narrow range of environmental conditions. Oligotrophic ecosystems are more sensitive (or less resistant) overall, to stress from nutrient enrichment. The most predictable outcomes are loss of sensitive species and increased abundance of generalist or opportunistic species that are more resistant to the undesirable water quality changes and other stresses affected by nutrient pollution. An ecosystem becomes more eutrophic (that is, increasingly stressed by eutrophication), it becomes more resistant to further change.

Increasingly eutrophic lakes, lower rivers, and estuaries are commonly characterized by seasonal low oxygen stress. Hypoxia and anoxia develop when oxygen consumption exceeds supply, as a result of two major factors. The algae—often in densities of millions to billions of cells/ml of water—often are the first food web component to be stimulated by nutrient enrichment. They are net producers of oxygen through photosynthesis during the day, but at night they consume oxygen for respiration. Dense populations of algae in the upper and mid-depths of the water column can consume most of the available dissolved oxygen. Low-oxygen stress in the system also occurs because of increased decomposition. As plants and animals die and settle out over the growing season, their remains are decomposed by bacteria and fungi in oxygen-demanding processes that can rapidly deplete the oxygen from the lower water column, sometimes extending to mid-depths or shallower. Oxygen solubility decreases with increasing temperature. Thus, low-oxygen stress tends to be most pronounced in warmer seasons when algal biomass, decomposition rates, and respiratory rates (and oxygen requirements) of fish and other animals generally are high.

Low-oxygen conditions are exacerbated when bottom waters become somewhat isolated from the upper water column that receives oxygen (i) during the day from phytoplankton growth, and (ii) throughout the diel cycle from the overlying air as it diffuses into the water, and from phytoplankton growth (during the day). The isolating effect occurs when the water column becomes thermally (density) stratified, as in the bottom water layer (hypolimnion) of a stratified lake, or salinity (density) stratified, as in the lower water-column salt wedge in an estuary. As a result, sessile bottom-dwelling animals become physiologically stressed and may suffocate unless they can slow their metabolism until oxygen is replenished. Mobile animals that rely on the bottom waters as critical nursery areas for their young, or as a refuge area to escape predation, can physically avoid the low-oxygen areas but may nonetheless suffer population declines because of critical habitat loss.

Organic matter in poorly treated sewage and animal waste contributes to low-oxygen stress in aquatic systems, as another source of material for decomposition or “biochemical oxygen demand.” Chemical oxygen demand may further deplete oxygen, through oxidation of high levels of ammonia and other inorganic reduced compounds in the wastes. These oxygen-demanding processes often are relatively localized problems oc-
EUTROPHICATION AND OLIGOTROPHICATION

653

 occurring, for example, near sewage outfalls or animal waste spills. In contrast, certain oxidized nutrients such as nitrate can be highly soluble in water and, therefore, can be transported considerable distances as shown, for example, by Mallin et al.’s work. This transport creates a time lag between the introduction of nutrients into one area and adverse impacts at some distance from the source. Oxygen consumption from decomposition of excess phytoplankton production thus can occur on a large scale that is difficult to track or to relate to one specific, original source.

II. CHANGES IN FLORA AND FAUNA

A. Microalgae

1. Species Shifts across Nutrient Gradients

Phytoplankton dominate the flora of oligotrophic systems (Fig. 2). They respond quickly to nutrient inputs because the tiny plantlike organisms are immersed in the enriched medium, in contact with it on all surfaces. Phytoplankton with optimal growth at elevated nutrient concentrations are especially stimulated or “selected for” by nutrient enrichment, and they eventually overgrow and replace species that grow best at lower nutrient levels. Along a nutrient enrichment gradient from oligotrophic to highly nutrient-enriched, the phytoplankton community structure gradually shifts from low abundance of many species and dominance by small flagellates and picoplankton (algae ≤ 2 μm in diameter), with energy flow channeled through a microbial loop of bacteria and small flagellates rather than directly up the food chain to herbivorous zooplankton, to high abundance of relatively few species consisting mainly of large cells or large colonies as well as seasonally abundant flagellates. As lakes, lower rivers, and estuaries become more eutrophic, diatom species with higher N and P optima predominate in colder periods, certain colonial green algae with high N optima are abundant in early summer, and dinoflagellates (Dinophyceae: Gymnodinium spp., Peridinium spp.) and filamentous and colonial cyanobacteria with high P optima dominate in late summer. If dissolved silica, needed by diatoms to make their cell walls, is limiting in colder seasons, flagellates (as examples, dinoflagellates, cryptomonads, euglenoids) become more abundant. In shallow freshwater lakes, estuaries and lagoons where open-water habitat is limited, high phytoplankton densities occasionally occur in response to nutrient enrichment (for example, high flagellate densities that historically occurred in response to excrement from duck farms in western Long Island Sound). More commonly, benthic algae known as epiphytes (growing on the leaves of submerged aquatic vegetation or SAV), or floating “drift” macroalgae (in sheltered estuarine and marine coastal embayments), are rapidly stimulated by the nutrient increases and restrict light for underlying plants (Figs. 2 and 3). Increased nutrient enrichment generally promotes a decrease in the species diversity of benthic, photosynthetic algae, and a shift in dominance from diatoms to filamentous green algae or coccoid cyanobacteria. The combination of low light and rich organic substrates, characteristic of planktonic and (more so) benthic habitats in such systems, also selects for mixotrophic microalgae, which become abundant and diverse under moderately eutrophic conditions.

Many regions of the world have landscapes domi-
EUTROPHICATION AND OLIGOTROPHICATION

FIGURE 3
Generalized shift in biomass of major plant groups with increasing nutrient inputs to shallow marine ecosystems. Occasionally the phytoplankton dominate, but usually macroalgae dramatically increase, while submerged rooted plants decline through competition for light and/or nitrogen. Reprinted from Harlin (1993), with permission.

...nated by run-of-river impoundment or reservoirs, rather than natural lakes. Similar trends in impacts from nutrient loading on aquatic communities can occur over time in reservoirs as in lakes, with the exception of depauperate rooted macrophyte populations (discussed later) in reservoirs with variable depth imposed by controlled drawdown involved in potable water supply management or flood control. Impacts of cultural eutrophication in reservoirs can be mitigated by rapid water exchange (weeks to months, rather than years in most natural lakes). Moreover, the high turbidity from sediment loading/resuspension, characteristic of many reservoirs and estuaries as well as some natural lakes, often makes available light—rather than nutrients—the primary resource limiting the productivity of phytoplankton and other flora in the systems. Nutrients act as secondary factors controlling plant growth under such conditions. Such systems often can sustain higher nutrient (especially P) loading than clear, natural lakes while supporting less phytoplankton biomass because of their features of more rapid water exchange and light limitation from high suspended sediments.

"Bottom-up" control by nutrients interacts with grazing pressure from zooplankton and other fauna in "top-down" trophic-level effects. Such effects are well documented in freshwater lakes and streams, and can also be operative in estuaries and coastal marine waters. Many field and laboratory studies have demonstrated that proliferation of phytoplankton and benthic microalgae under nutrient enrichment (for example, seagrass epiphytes as described by Neckles and colleagues) can be significantly reduced during periods when grazers are abundant. Thus, herbivores can sometimes alleviate eutrophication impacts by holding algal production in check. Decreased grazing pressure can allow higher algal biomass to develop in response to excess nutrients, but decreases in grazing can help promote algal blooms only where nutrient inputs are sufficiently high to support such blooms. Therefore, grazing pressure is regarded as a secondary factor controlling phytoplankton production under cultural eutrophication.

2. Long-Term Human Influence
Long-term data sets have provided two lines of compelling evidence in support of major impacts from cultural eutrophication on phytoplankton assemblage structure in aquatic ecosystems, with potentially serious ecological and economic ramifications. First, the geological record in sediment cores taken from many freshwater lakes and estuaries clearly shows that long-term major shifts have occurred under increased nutrient enrichment—progressing from a balance between species-rich planktonic (mostly centric) and benthic (mostly pennate) diatom assemblages, to dominance by plank-
tropic diatoms with low species diversity (Fig. 4). Planktonic diatoms are selected for because they are the early recipients of water-column nutrient sources. Benthic diatoms encounter decreased light because of the overlying planktonic growth, eventually leading to decreased production.

The second line of evidence concerns living phytoplankton assemblages with species shifts that have been related to changes in supply ratios of the two most limiting nutrients. Under nutrient-limiting conditions, species with similar optima in other environmental factors (for example, temperature or light) that maintain faster growth compete more successfully for the available nutrient resource (Figs. 5–7). Elegant work by Tilman and colleagues examined the response of freshwater diatom species to shifts in Si : P ratios. Rhee and colleagues extended these concepts to controlling influences of N : P ratios. Low molecular N : P ratios (7–15 in those studies; up to ca. 29 : 1 by weight in Smith’s work) favored tested blue-green and diatom species, whereas higher N : P ratios favored green algae. Many green algae grow optimally at high N, concentrations, whereas many blue-greens and dinoflagellates have a high P requirement. Diatoms, unlike the other algae, require major supplies of silica as well as N and P. When Si : N and Si : P ratios are high, the available Si favors growth of diatoms that can effectively compete for N and P resources. However, as Si : N and Si : P ratios decrease, silica becomes limiting for diatom growth, and more N and P remain available for growth of flagellates and other algae that do not require silica. These concepts were extended to natural lakes by Tilman and colleagues (for diatoms and other algae), Smith (for blue-greens), and others.

Silica is only slowly (years) made available for new diatom growth, through dissolution of dead diatoms and other natural silica sources. In contrast, N and P cycles are rapidly affected by anthropogenic inputs. As N and P enrichment increase, the Si : N and Si : P supply ratios are depressed. Eutrophication can effect a decrease in dissolved Si abundance by initially stimulating high growth of diatoms, to the point that they deplete the dissolved silica pool needed by developing diatom populations in subsequent seasons. Long-term data sets on estuarine, coastal, and freshwater phytoplankton communities indicate that shifts to dominance by flagellated algae or blue-greens—including some harmful bloom-forming species—have coincided with decreased abundance of diatoms and decreased Si : N and Si : P ratios. Such trends have been documented by Smayda and others in temperate and sub-Arctic waters such as the Great Lakes, the Gulf of Mexico near the mouth of the Mississippi River, New England coastal waters, Chesapeake Bay estuarine waters, the Black Sea, and the coasts of northern Europe.

In oligotrophic tropical marine waters, mixotrophic dinoflagellates tend to predominate and symbiotic interactions are common in both planktonic and benthic communities. Little is known about impacts of eutrophication on phytoplankton community structure in such systems, but it is hypothesized that increased nutrient enrichment would shift the community structure to higher proportions of flagellated photosynthetic algae with less reliance on heterotrophy or symbiosis. Trace metals such as iron have also been shown to be limiting to phytoplankton growth in some estuarine and marine waters, where N and P are at levels that would otherwise be expected to support more algal production.

As eutrophication progresses, the previously described shift in temperate-zone phytoplankton community structure from certain diatoms to other diatom species, flagellates, and cyanobacteria causes subtle, but important, undesirable changes for the food web that can adversely affect secondary production. For example, as reviewed by Kilham and colleagues, some diatom species produce high quantities of certain lipids that are essential for zooplankton reproduction. Algal species that may replace these diatoms under increasingly eutrophic conditions do not produce these lipids, or produce much fewer of them. Analogous phenomena occur in fresh waters, estuaries, and coastal environments. For example, Starr and colleagues reported that spawning of green sea urchins and blue mussels apparently is triggered by a heat-stable metabolite that is released in high abundance by certain species of phytoplankton, especially certain diatoms such as Skeletonema costatum (Bacillariophyceae). This substance is not produced, or is produced in much lower quantities, by flagellated algae that replace these diatoms under cultural eutrophication.

3. Harmful Algal Blooms and Anthropogenic Nutrient Enrichment

Among the algal species favored by nutrient enrichment are noxious forms such as cyanobacteria that are toxic to zooplankton, fish and wildlife in fresh waters and certain estuaries (Baltic Sea and Australia), and certain dinoflagellates that are toxic to finfish and shellfish in estuarine and marine coastal areas worldwide (Table I). For example, the two known toxic Pfiesteria species have been most active in waters degraded by poorly treated sewage, swine effluent spills, and other excessive nutrient inputs, and these organisms have been experimentally stimulated by nutrient enrichment. However,
The geological record of cultural eutrophication in Chesapeake Bay, showing major changes since European settlement. The data from four sediment cores are graphed by the average date assigned to each sediment sample (depth layer) according to radiocarbon and pollen methods. (a) Total organic carbon (TOC, indicating total system productivity) preserved over time (historic record from A.D. 150 to A.D. 1990). Modified from Cooper and Brush (1991), with permission. (b) Diatom cell numbers per year (A.D. 400 to A.D. 1990). (c) Diatom community diversity calculated as Shannon's H (A.D. 400 to A.D. 1990). (d) Centric/pennate diatom ratios (A.D. 400 to A.D. 1990). TOC, diatom numbers, and the centric/pennate diatom ratios all showed a significant and abrupt increase following the time of European settlement in the 1700s. The total diatom community diversity, in contrast, significantly decreased post-1700s, relative to pre-1700s diversity. Graphs b–d were modified with permission from Cooper © (1999) American Association for the Advancement of Science.
EUTROPHICATION AND OLIGOTROPHICATION

FIGURE 5 The outcome of competition between diatoms for limiting nutrients (silica or phosphate) across a gradient of Si : P ratio comparing two freshwater planktonic diatoms, Cyclotella meneghiniana and Asterionella formosa, under growth-limiting conditions (temperature, light, and other conditions held constant). These chemostat culture experiments indicate conditions in which A. formosa is dominant because it can outgrow C. meneghiniana at very low P (as micromolar concentrations or micromoles per liter of phosphate, μM P3), conditions wherein the two species can coexist (circles) because one is limited by P, and the other is limited by Si (as silicon dioxide concentrations, μM SiO2); and conditions wherein C. meneghiniana can dominate because it can outgrow A. formosa at lower Si. Reprinted from Tilman (1982), with permission.

Other species of harmful algae are found in oligotrophic waters and do not appear to be favored by elevated nutrients. The planktonic Gulf Coast red tide dinoflagellate, Gymnodinium breve, and certain benthic toxic dinoflagellates that inhabit coral reefs (Gambierdiscus toxicus, Prorocentrum lima) are among various harmful species that have been reported to achieve optimal growth in low-nutrient conditions.

Despite their economic impacts worldwide, remarkably little is known about the nutritional ecology of most species of estuarine and marine toxic, parasitic, and other harmful algae. Overgeneralizations should be avoided that prematurely negate the potential for stimulation of various other harmful/toxic estuarine and marine algae by nutrient enrichment. As additional species are thoroughly evaluated, it will be important to consider that the concentration of a nutrient at any given point in time may not be correlated with its actual bioavailability, and that phytoplankton can grow for long periods on internally stored (luxury-consumed) nutrients.

FIGURE 6 The outcome of competition among diatoms, green algae, and blue-green algae for limiting nutrients (nitrogen or phosphorus) across a gradient of N : P ratios under silica-replete (nonlimiting) conditions, showing additional influence of temperature. The comparison includes representative species of freshwater lake diatoms (circles), green algae (triangles), and blue-greens (cyanobacteria; diamonds) in chemostat culture under growth-limiting conditions for N and P (but not for Si). Note that at the coldest temperature indicative of conditions during spring and fall seasons in this north temperate lake, the cold-optimal diatoms outcompeted the greens and blue-greens across all N : P ratios. That is, temperature, rather than N or P, was the most important condition limiting the growth of greens and blue-greens relative to diatoms. The midrange temperature represented a transitional area where some growth could occur for species representing each group. The highest temperature favored warm-optimal blue-greens (that tend to have high P optima), especially at low N : P ratios when P was more abundant. Reprinted from Harper (1992), with permission; originally modified from Tilman et al. (1986).
FIGURE 7  The outcome of competition among diatoms, green algae, and blue-green algae for limiting nutrients (phosphorus or silica) across a gradient of P : Si, showing the influence of temperature. The outcome of competition is indicated among freshwater lake diatoms (circles), green algae (triangles), and blue-greens (cyanobacteria; diamonds) in chemostat culture under growth-limiting conditions for Si (needed only by the cold-optimal diatoms) and P at two temperatures. At the lower temperature, cold-optimal diatoms dominated across all Si : P ratios. However, at the higher temperature they were able to dominate over green algae only at high Si : P ratios, when their Si requirements were alleviated by the relatively high Si. The blue-green species were able to outcompete the other groups only at one transitional Si :P ratio even at the higher temperature, which was still suboptimal for these organisms. Reprinted from Harper (1992), with permission; originally modified from Tilman et al. (1986).

nutrient pools. The luxury consumption and subsequent use of inorganic N, P, and C; the cell budgets for these nutrients; and the role of heterotrophy (including indirect stimulation by nutrient enrichment, through increased growth of microbial prey) in supplying carbon to be examined for most harmful estuarine and marine species.

B. Macroalgae

1. Freshwater Assemblages

The major flora of certain aquatic habitats are macroalgae, and they include some notorious aquatic “weeds” that respond to cultural eutrophication. Temperate-zone freshwater, oligotrophic hard-water lakes may contain abundant benthic charophytes and, rarely, a few species of small brown macroalgae (Phaeophyceae). Oligotrophic soft-water lakes may have populations of small, benthic red macroalgae (Rhodophyceae), especially near spring-fed areas with bubbling carbon dioxide. As eutrophication progresses, populations of certain filamentous green algae and cyanobacteria that would otherwise be considered as microalgae become visually common, especially under high P enrichment. For example, Cladophora glomerata (Chlorophyceae) forms masses of long hairlike growth (dominant during the 1960s in the littoral zone of the west basin of Lake Erie); and cyanobacteria (or blue-green algae, Cyanophyceae; for example, Anabaena, Aphanizomenon, Microcystis) form tufts or amorphous masses of greenish, bluish-green, or reddish gray slime.

Macroalgae are the dominant autotrophs of midorder streams where hard substrata are available for colonization and light is moderate to high, especially after leaf fall in colder seasons. Stream-inhabiting macroalgae are often much more diverse and abundant than lake macroalgal floras. Nutrient-poor (often soft-water) stream segments are colonized by diverse, abundant cold-optimal chrysophytes (e.g., Eunotia pectinalis [Bacillariophyceae], Tetrasporopsis [Chrysophyceae]), green algae (Spirogyra, Tetraspora, Oedogonium), red algae (Batrachospermum, Paralemanea [Rhodophyceae]), or cyanobacterial mat formers (Phormidium). As eutrophication progresses, soft waters may develop larger populations of filamentous green algae such as certain species of Oedogonium and Mougeotia or dense growth of colonial Hydrodictyon and Stigeoclonium (also known to tolerate high metal concentrations that may be found in poorly treated sewage). Hard-water streams under high P enrichment may become choked with massive growth of Cladophora spp.

2. Estuarine and Marine Assemblages

Macroalgae also dominate the flora of many shallow estuaries, lagoons, and upper embayments, coral reefs, and rocky intertidal/subtidal habitats (Fig. 3). Nutrient enrichment leads to reduction in the diversity of macroalgae and associated fauna. Opportunistic species of green algae within the genera Enteromorpha (also found in saltwater lakes such as the Great Salt Lake of Utah), Ulva and Cladophora, and within the brown algal genus Ecklonia have rapid growth rates and proliferate because they can more quickly take advantage of the ele

</tbody>
</table>

Note that many of the known harmful estuarine and marine microalgae and heterotrophic or animal-like dinoflagellates also have been shown to be stimulated by N or P enrichment in culture, expected since they are photosynthetic. Also note that blooms of the toxic *Pseudo-nitzschia* complex have not been associated with cultural eutrophication in the northwestern United States. Reprinted from Burkholder (1998), with permission.

\[ \text{Ammonium is more readily used (less energetically costly)} \text{ than nitrate, but either N form has significantly stimulated growth of opportunistic macroalgae in field research and mesocosm experiments. Phosphate can stimulate macroalgal growth when N is abundant.} \]

For example, in Boston Harbor, Massachusetts, sea lettuce (*Ulva*) formed dense populations for many years near outfalls of poorly treated sewage. The massive seaweed growth reduced water flow, smothered shellfish, and affected shoreline areas with an intolerable...
stench of hydrogen sulfide from decomposition of senescent/dead material. In Peel/Harvey Estuary, Aus-
tralia, dense mats of Cladophora, other green macroal-
gae, and cyanobacteria developed in response to P load-
ing. In seagrass meadows worldwide, such overgrowth has been documented to reduce light and promote de-
clines in various seagrass species. Along the intertidal area of the Baltic Sea, sewage inputs have been related to overgrowth of formerly dominant brown seaweeds (Fucus spp.) by opportunistic macroalgae.

In subtidal outfalls, nutrient enrichment from sewage and other wastes has stimulated overgrowth by red algae such as certain species of Polysiphonia. The exotic green macroalga Caulerpa taxifolia is a subtidal, sub-
tropical “weed” that has invaded colder waters of the Mediterranean, and sewage appears to further stimulate its robust growth. This organism produces metabolites that discourage predation; sea urchins typically avoid consuming C. taxifolia and starve to death if it is the only available food. Subtidal forests of giant kelp (Mac-
rocystis pyrifera) died back and failed to reproduce dur-
ing the 1960s and 1970s near outfalls of sewage dis-
charged from Los Angeles. The kelp bed loss apparently resulted from toxic substances in the poorly treated sewage.

Sensitive oligotrophic coastal marine coral reefs have been overgrown and smothered by macroalgae after nutrient input from sewage. In Kaneohe Bay, Hawaiis, for example, phytoplankton near sewage outfalls first removed the N and were transported to the central area of the coral reef where they decomposed and released the N for stimulation of the opportunistic green macroalga, Dictyosphaeria cavernosa. Inorganic nutrient concentrations are frequently below detection in natural coral reef waters. Lapointe’s elegant work indicated that even minor sewage-related increases in N (≥1 μM) and P (0.1–0.2 μM soluble reactive phosphate) off the coast of Jamaica, together with decreased herbivory from natural and fishing-related disturbance, were suffi-
cient to stimulate blooms of the green “eutrophic indi-
cator” macroalga, Chaetomorpha linum and cyanobacte-
ria that have overgrown coral reefs in that area.

Reduced light from such excessive nutrient-stimu-
lated macroalgal (and sometimes phytoplankton) growth affects coral growth by decreasing the produc-
tivity of zooxanthellae, the symbiotic photosynthetic dinoflagellates inside the coral tissue that provide much of the corals’ nutrition. Nutrient overenrichment also can shift species dominance within the coral commu-
nity. As the corals are outcompeted for space, filter-
feeding taxa such as sponges may be stimulated by increased phytoplankton food resources, and they can replace corals as dominant species. Sedimentation of decomposing phytoplankton, and other disturbances such as destructive techniques for fish harvesting, can exacerbate the impacts of cultural eutrophication on coral growth and survival.

C. Aquatic Macrophytes

1. Freshwater Communities

Floating, submersed, and emergent aquatic vascular plants, commonly called macrophytes, respond to nutrient enrichment in different ways because the compet-
titive forces that they encounter vary with plant growth habit. Rooted plants—including those with specialized floating leaves, submersed growth, or emergent growth—generally do not compete with phytoplankton and other algae for nutrients, because they obtain most nutrients (except carbon, taken from the water) from the nutrient-rich sediment, with leaf uptake of nutrients from the less enriched overlying water as a secondary nutrient source. In contrast, floating plants at the water surface, such as the Lemnaceae (duckweed family) and the exotic weed Eichhornia crassipes (water hyacinth), must compete with suspended algae for N and P, but rely upon the overlying air for their carbon. Floating submersed plants must compete with suspended algae for all major nutrients. They tend to have well-devel-
oped root systems to aid in nutrient acquisition, and in shallow waters with sparse open-water habitat, they can outcompete phytoplankton for light by forming dense surface populations that reduce or eliminate available light in the underlying water. However, sub-
mersed rooted aquatic vegetation (SAV) is usually elimi-
nated in highly eutrophic systems, primarily through light reduction by phytoplankton and other algal over-
growth, as described by Phillips and colleagues, Wetzel, and others (Fig. 2).

Like stream-inhabiting macroalgae, rooted macro-
phytes in river systems reach maximal abundance and species diversity in midorder segments. But, in contrast to lake-inhabiting macroalgae, submersed freshwater macrophyte communities attain highest spe-
cies richness and abundance in mesotrophic lakes, often with dominance by Potamogeton spp. Light plays a ma-
jor role in progressive SAV decline as lakes become increasingly eutrophic. Nutrient enrichment can stimu-
late macrophyte growth through luxury uptake and tight recycling, sometimes without an increase in phyto-
plankton. Over time, however, epiphytic algae take ad-
vantage of the greatly increased surface area for coloni-
zation afforded by the macrophytes, and they can both
2. Estuarine and Marine Macrophyte Communities

Brackish waters are colonized by rooted, mostly fresh-water species with moderate salt tolerance (as examples, certain Potamochiron spp., Valvularia americana, Zanichellia spp.). In such habitats, light is often the primary resource limiting growth. Species with broader salt tolerance such as Ruppia maritima also can be abundant. Only about 50 species of angiosperms, mostly close relatives of freshwater Potamogeton spp., have the salt tolerance needed to thrive in marine habitats. Nearly all of these “seagrasses” grow in muddy substrata of shallow coastal lagoons and quiet embayments. Estuarine and marine macrophytes tend to be highly sensitive to light reduction and, thus, susceptible to eutrophication-related turbidity from algal (phytoplankton, epiphyte, and macroalgae) overgrowth and sediment loading/resuspension. Such shading causes gradual dieback and loss of most SAV, promoting dramatic declines, in turn, in the diversity and abundance of many plant and animal species that depend on the habitat provided by these plants.

More sensitive SAV species are replaced by others that are tolerant of eutrophic conditions. For example, among subtropical seagrasses, field observations and limited experiments have indicated that turtle grass (Thalassia testudinum) is more sensitive to eutrophication than shoal grass (Halodule wrightii) and manatee grass (Syringodium filiforme). Other regions may not have additional seagrass species available to replace more sensitive species and, where such species are present, they typically offer less desirable fish nursery habitat than the former dominant. Thus, in seagrass meadows under nutrient over-enrichment, more oligotrophic seagrass species are replaced by less sensitive species when available. As eutrophication progresses the seagrasses are eliminated, and rapidly growing macroalgae or phytoplankton become the dominant flora (Fig. 3).

Although light reduction is considered the major mechanism for seagrass decline under cultural eutrophication, excessive nutrients can act independently of light to promote seagrass loss (Fig. 8). The dominant north temperate species, elgergrass (Zostera marina), apparently lacks a physiological mechanism to inhibit nitrate uptake through its leaves, as indicated by the research of Pregnall, Burkholder, and colleagues. Most plants take up nitrate during the day with energy from photosynthesis. In contrast, Z. marina takes up water-column nitrate day or night if it becomes available, as shown by Touchette and colleagues (Fig. 9). This species probably evolved in N-poor coastal waters, and sustained nitrate uptake under temporary enrichment may have developed as a once highly advantageous competitive strategy. However, as coastal waters have become more eutrophic from sewage, septic effluent...
FIGURE 8 The effects of water-column nitrate enrichment and light reduction on shoot production of the seagrass, *Zostera marina*. From author's outdoor mesocosm experiments, indicated as the percent decrease from shoot production of control plants that did not receive water-column nitrate additions or light reduction (except that plants in controls and treatments all received an additional 30% light reduction for 3 hr at 0900, 1200, and 1500 hr on a 3-day rotation using neutral density screens to simulate conditions during high tide). Treatments were imposed for 10 weeks during the fall growing season for *Z. marina*. Controls were maintained at ambient natural light (except during simulated high tide) and nitrate (50 μg NO₃⁻/L). Treatments included low N (at 50 μg NO₃⁻/L, added daily as a pulse of enrichment) and high N (at 100 μg NO₃⁻/L) at each of three imposed light levels as 30, 50, or 70% reduction of ambient surface light (*Io*, accomplished using neutral density shades, with additional shading at simulated high tide as noted). *Z. marina* in all treatments with water-column nitrate enrichment declined in shoot production relative to shoot production of control plants, and the nitrate inhibition effect was exacerbated by light reduction (means ± 1 standard error; *P* < 0.05, *n* = 3). These effects were not caused by algal overgrowth, which was maintained at low levels in controls and all treatments throughout the experiment.

leachate, and other anthropogenic sources, sustained uptake of water-column nitrate likely has become a disadvantage. Nitrate enrichment to the sediments, under control by an abundant microbial consortium, does not cause a similar effect and, instead, can be mildly stimulatory.

Nitrate uptake is a metabolically expensive process, requiring high cellular energy. Research by Touchette and colleagues indicated that sustained water-column nitrate uptake by *Z. marina* can promote severe internal carbon imbalances, apparently from the need to shunt C skeletons from photosynthesis for use in high amino acid synthesis to prevent internal accumulation of toxic products such as ammonia. The physiological mechanism of an internal “carbon drain” from sustained nitrate uptake has been documented (for algae) by Turpin and colleagues. A common trait of *Z. marina* shoots under excessive water-column nitrate enrichment is structurally weakened growing regions, perhaps analogous to the above-mentioned loss of stem strength that has been reported in certain freshwater emergent macrophytes under nitrate enrichment. Excessive N enrichment has also promoted seagrass attack by pathogens (for example, the slime mold Labyrinthula zostericola), hypothesized to occur because N and C are internally shunted to amino acid production rather than to production of alkyloids and other antimicrobial compounds.

Another seagrass that has been examined for the nitrate inhibition phenomenon, *Halodule wrightii*, and certain macroalgae (for example, *Ulva lactuca*) have shown depressed growth in response to nitrate enrichment, although at much higher N levels (ca. 1.4 mg NO₃⁻/L, pulsed daily for 4 to 5 weeks) than for *Z. marina* (50–110 μg NO₃⁻/L, pulsed daily for 3 to 8 weeks). *Ruppia maritima* is stimulated by high water-column nitrate but inhibited by elevated N, as ammonia;
and Z. marina has been experimentally inhibited by high ammonia levels as well. In mesocosm experiments, light reduction has been shown to exacerbate the inhibitory effects of water-column nitrate enrichment on shoot production in Z. marina. Warm temperatures also exacerbate water-column nitrate enrichment impacts on root growth of this seagrass, suggesting that warming trends in climate change may be expected to interact with eutrophication and adversely affect this beneficial habitat species.

D. Microfauna

1. Freshwater Communities

Whereas plants and mixotrophic algae respond directly to nutrient enrichment, animals are generally indirect recipients of eutrophication impacts. Nonetheless, all are significantly affected by nutrient control of the quality (including size, taste, and ease of filtering) and quantity of their algal, bacterial or detrital food. Freshwater zooplankton consist of three main groups: (i) protozoa (mainly ciliates and flagellates) and (ii) rotifers form the "microzooplankton" (maximum dimension ca. 45 μm to less than 70 μm); and (iii) crustaceans form the "macrozooplankton" (mainly cladocera, and calanoid and cyclopoid copepods, ca. 70 μm to less than 500 μm). Protozoa diversity and abundance increase with the amount of available organic matter that becomes directly or indirectly available through eutrophication until the fauna are restricted by low-oxygen conditions. Oligotrophic protozoan plankton can be dominated in number by small-bodied ciliates, whereas large ciliates generally contribute most of the biomass (especially members of the Oligotrichida such as Phagotrypa nasuta and Paramecium rictum). Mesotrophic and eutrophic lakes are more commonly dominated in both number and biomass by small-bodied species (e.g., member of the Scuticociliatida). Protozoans are relatively sparse in oligotrophic lakes in comparison to the species-rich and abundant fauna that develops in moderately eutrophic waters. Aggregates of bacteria and detritus form in the water column as organic materials decompose, and these microhabitats can support protozoa that rival shallow benthic communities in diversity. Subtropical lakes show similar trends, but have been reported to support higher ciliate abundance and diversity than shallow lakes at a given trophic status.

Heterotrophic flagellates in the water column are bacterivores, whereas larger ciliates and heliozoa commonly consume mixed populations of heterotrophic and autotrophic flagellates and other algae. In low-oxygen waters, heliozoan amoebae and ciliates such as Coleps and Euplotes retain endosymbiotic green algae (zoochlorophyceae) that photosynthesize and generate oxygen for their hosts. As nutrient enrichment increases, bottom waters and surface sediments become more organically enriched; but the physiological demands on protozoans and other microfauna such as certain rotifers are also greater. Survival generally depends on tolerance of low-oxygen and often co-occurring acidic conditions. In organically overloaded, hypoxic sediments, protozoa species diversity is very low relative to that in well-aerated sites. Bacteria and dissolved organic matter form the major food sources, and are consumed by species such as Paramecium, Chilomastus, and Astasia. Anoxic sediments become colonized by specialized protozoa such as pelobionts and diplomonads, and by certain ciliates and amoebae.

Rotifers include many algal herbivores as well as detritivores and a few carnivorous species. They generally attain highest species diversity and abundance, along with increasing small-celled phytoplankton, in moderately eutrophic lakes and lower rivers. These microzooplankton tend to be favored in abundance over macrozooplankton under increasing eutrophication. However, rotifer species diversity declines as eutrophication progresses to phytoplankton dominance by cyanobacteria, especially large mucilaginous colonial species that clog the filtering apparatus of the animals. Rotifers are adversely affected as well by the toxins from certain cyanobacteria that are seasonally characteristic of eutrophic lakes.

Among macrozooplankton, cyclopoid copepods (raptorial feeders) generally feed most efficiently on larger "particles" (for example, algae with biovolume ≤1,000 μm³), whereas calanoid copepods consume particles ≤100 μm³, and cladocerans eat small particles at ca. 10 μm³. Changes in biodiversity under cultural eutrophication depend, to a large extent, on differences among these species in efficiencies of feeding at certain particle (algal or detrital) concentrations and size ranges, and on the responses of life history stages to food limitation. Nutrient enrichment alters food particle size and abundance which, in turn, leads to competitive species displacement. Larger-bodied individuals are often more efficient filter feeders than smaller fauna. However, larger species may not be competitively superior because their juveniles tend to be more vulnerable to food limitation than adults of smaller species. Smaller species withstand food depletion by reducing metabolism, growth, and egg production. Moreover, their specific food ingestion rate (milligrams food ingested per milligram of zooplankton biomass) is usually higher than that of larger zooplankton.
Calanoid copepods (for example, *Eudiaptomus*) often dominate the microfauna of oligotrophic and mesotrophic lakes. These organisms feed efficiently on larger algal cells in those systems, with higher ingestion efficiencies at low food density. As algal prey densities increase under eutrophication, larger cladoceran species become abundant under low to moderate predation by fish, whereas high predation tends to select for smaller cladocerans such as *Bosmina* or *Ceriodaphnia* over *Daphnia*. The larger cladoceran species generally have higher population growth rates than calanoid copepods. Their population cycles during warmer months have been shown to be mainly controlled by the relative proportions of edible and inedible algae, temperature, and predation. Like rotifers in the presence of abundant food, cladocerans can reproduce parthenogenetically, thus allowing for rapid growth rates. They are more efficient filter feeders at moderate to high algal densities because they ingest more food for the same amount of energy expended, relative to ingestion under food-limited conditions. Macrozooplankton biomass increases under eutrophication in both temperate and tropical lakes, with increasing dominance by small-bodied species. High-efficiency bacterial feeders are selected for as bacterial abundances increase under accelerated eutrophication. However, abundant co-occurring cyanobacteria with copepods may clog the filtering apparatus of large-bodied microzooplankton. Moreover, some cyanobacteria are directly toxic to these fauna. In highly eutrophic lakes, the more selective feeding of calanoid copepods, and the seizing behavior of herbivorous cyclopoid copepods, may afford one or both groups competitive advantage. Smaller cladocerans, such as the littoral-zone chydrorid *Chydorus*, may increase under eutrophication, larger cladoceran species generally have higher population growth rates than calanoid copepods. Their population cycles during warmer months have been shown to be mainly controlled by the relative proportions of edible and inedible algae, temperature, and predation. Like rotifers in the presence of abundant food, cladocerans can reproduce parthenogenetically, thus allowing for rapid growth rates. They are more efficient filter feeders at moderate to high algal densities because they ingest more food for the same amount of energy expended, relative to ingestion under food-limited conditions. Macrozooplankton biomass increases under eutrophication in both temperate and tropical lakes, with increasing dominance by small-bodied species. High-efficiency bacterial feeders are selected for as bacterial abundances increase under accelerated eutrophication. However, abundant co-occurring cyanobacteria with copepods may clog the filtering apparatus of large-bodied microzooplankton. Moreover, some cyanobacteria are directly toxic to these fauna. In highly eutrophic lakes, the more selective feeding of calanoid copepods, and the seizing behavior of herbivorous cyclopoid copepods, may afford one or both groups competitive advantage. Smaller cladocerans, such as the littoral-zone chydrorid *Chydorus*, may become abundant during dense cyanobacteria blooms because of their high efficiency in filtering the extremely small, solitary bacteria and blue-green prokaryote particles associated with the blooms while avoiding filter apparatus clogging by large, mucilaginous cyanobacteria colonies. Eutrophication can cause other impacts on zooplankton species, apart from changes in available food. For example, as bottom waters become increasingly hypoxic, survival is depressed for zooplankton eggs that sink to the bottom as part of the life cycle. Thus, nutrient enrichment can impair zooplankton recruitment as an indirect impact.

2. Estuarine and Marine Communities

Impacts of anthropogenic nutrient loading have, understandably, been more difficult to generalize in the complex flow/water exchange environments of estuaries and from large-scale marine environments with high physical and biological variability. Analyses by Michell and others have indicated that nutrients generally enhance phytoplankton biomass and carnivores depress herbivore biomass, but that the couplings between trophic levels (for example, phytoplankton and zooplankton) are weaker than in more "closed" systems (lakes and coastal lagoons). Brackish and marine habitats differ from fresh waters in having fewer rotifers or cladocera, more extensive representation by protozoans (especially ciliates and foraminifers), and often-abundant planktonic nauplii (young life history stages) of sessile adult fauna ranging from mollusks and malacostracan crustaceans to vertebrates. Holoplankton spend their entire lives in the water column. Among these are microzooplankton including larval forms of certain macrozooplankton, as well as tintinnid and non loricate ciliated protozoans, heterotrophic flagellates, and amoebozooe. In benthic habitats, the “meiofauna” (similar in size to microzooplankton) include nematodes, harpacticoid copepods, many turbellarians, and several minor phyla with diverse feeding habits and lifestyles, mostly acting as consumers of other microbes as prey. Macrozooplankton include copepods, especially of the genus *Acartia*, other cyclopoid copepods and planktonic harpacticoids, noncopepod crustaceans (especially carideans and mysids), and chaetognaths (arrow worms). Meroplankton, which spend only part of their lives in the plankton as larval stages, may include immature forms of benthic invertebrates and tunicates; eggs, larvae, and juveniles of shrimp, crabs, and fish; and sexual stages of hydroidozoans and scyphozoan ctenoidea (jellyfishes). The microzooplankton are important phytoplankton herbivores among estuarine and marine zooplankton. They are strongly influenced by changing phytoplankton food quality and abundance under eutrophication, with trends that are somewhat analogous to those described for freshwater microzooplankton. Zooplankton species diversity is highest in moderately nutrient-enriched waters, but significantly declines as nutrient enrichment becomes more excessive, with accompanying shifts to dominance of unpalatable algal species and pronounced bottom-water oxygen deficits. For example, in the Peel-Harvey Estuarine System of Australia, large populations of calanoid copepods *Haliclymenia* and *Calanoides* grazed winter diatom blooms but were rapidly eliminated when the noxious (toxic) filamentous cyanobacterium, *Nodularia spumigena*, became abundant. Predation of carnivorous macrozooplankton by planktivorous fish such as menhaden (*Brevortia tyrannus*)...
Eutrophication and Oligotrophication

E. Invertebrate Macrofauna

The freshwater zoobenthos, or bottom macrofauna (>0.5 mm, or 500 μm), consists mostly of insect larvae (with terrestrial adult stages), crustacea, worms, and mollusks. Eutrophication in the littoral zone of lakes and rivers, with accompanying organic pollution, causes similar impacts on the invertebrate macrofauna of these systems. In early stages of eutrophication, oligochaetes, chironomids, gastropods, and sphaerids increase, and mayfly nymphs such as Hexagenia decrease. As eutrophication continues, the major change that coincides with progressive hypoxia/anoxia in overlying waters and surface sediments is the decline and then disappearance of additional oxygen-sensitive species such as stonefly (Diasca spp.) and certain other taxa of mayfly nymphs (e.g., Baetis, Rhiithrogena) as well as certain caddisfly larvae (e.g., Rhyacophila, Hydropsyche) and bivalve mollusks.

Eutrophication increases organic matter and bacterial decay and depresses oxygen concentrations while increasing settlement of organic detritus to benthic organisms such as certain flatworms (e.g., Polycelis) that use the detritus for food. In the profundal sediments underlying deeper waters of lakes, the macroinvertebrate biomass increases but is comprised of low oxygen-tolerant species such as certain chironomid larvae and oligochaete worms (e.g., the oligochaete Tubifex tubifex, which, in one study, survived, grew, and reproduced under continuous anoxia for 10 months). The species diversity of tubificid oligochaetes decreases with advanced eutrophication and organic enrichment, and associated oxygen deficits. However, if oxygen is periodically available, the rich food supply in combination with the lack of more oxygen-sensitive competitors allows robust growth. Declines in chironomid communities occur most rapidly in the change between nutrient-poor to moderately nutrient-enriched (mesotrophic) waters; and numbers of oligochaetes (relative to chironomids) increase as organic enrichment increases. In the intermediate zone between the littoral and profundal, the increased supply of "fresh" littoral detritus is consumed by large-bodied detritivores such as the bivalve mollusk Dreissena.

Estuarine and marine coastal invertebrate macrofauna, including mollusks, polychaetes, decapods, and other crustacea, and nemertean, spend their adult lives buried beneath the sediment surface. They are highly diverse with food acquisition as filter feeders, nonselective deposit feeders, selective deposit feeders, or raptorial/other predators, making generalizations difficult. Increasing organic matter from accompanying nutrient enrichment tends to cause similar impacts as in freshwater systems, namely, an increase in macroinvertebrate abundance under moderately eutrophic conditions, and a decline in species diversity and abundance as eutrophication and associated hypoxia/anoxia progress. Organisms that burrow into anaerobic sediments must be able to gain access to oxygen in the overlying water. Increasing eutrophication leads to elimination of burrowing organisms as the anaerobic zone moves closer to the sediment surface. In highly overenriched areas, only worms such as Capitella may survive. Oxygen does not need to be completely absent for damage to occur—hypoxic waters with 3.0 to 4.3 mg DO/L have been related to mortality of some benthic invertebrate species and to loss of habitat for shellfish species such as lobster that require higher oxygen availability.

Changes in food quality/quantity also can reduce the species diversity and abundance of estuarine and coastal marine invertebrate macrofauna under highly eutrophic conditions. For example, an extensive early study by Filice in San Francisco Bay demonstrated that in domestic sewage outfall areas, few species survived. Species diversity was higher but still depressed in surrounding areas that received dilute sewage. However, in those areas, some species (e.g., the clams Gemma gemma, Mya arenaria, and Macoma balthica) apparently took advantage of new energy and material resources, and became highly abundant relative to abundance in control areas without sewage influence. In the Great South Bay complex of
Long Island, New York, previously mentioned duck farms along the bay tributaries fertilized the water with nutrients and organic wastes, and stimulated dense blooms of the small algae, *Nannochloris* sp. and *Stichococcus* sp. (densities greater than $10^6$ cells/ml). These algae were very different from the previous phytoplankton community in the area, which consisted of mixed species that are needed to support oysters. Following these changes, oyster populations significantly declined, apparently because they were unable to thrive on a diet consisting only of these small algae.

**F. Vertebrate Macrofauna**

Eutrophication initially reduces and then eliminates sensitive lake fishes (e.g., salmonids and coregonids), by eliminating oxygen-replete, colder bottom-water habitat and well-oxygenated spawning areas. Fish can avoid low-oxygen waters, but the cold-optimal species encounter warmer waters as they are forced to move from deep areas into the shallows. Most temperate-zone fishes breed in the littoral. Their eggs are more vulnerable to short-term (e.g., nightly) oxygen deficits and to the low-oxygen microenvironment of increased detritus. Thus, the critical habitat of these sensitive species is destroyed by nutrient overenrichment, and spawning and recruitment are depressed.

Analogous impacts occur in rivers and estuaries. For example, in parts of the Baltic Sea, cod eggs laid in well-oxygenated surface waters die when they sink to anoxic bottom waters. Oxygen levels in the bottom waters of the Baltic’s deep basins are negatively correlated with juvenile codfish abundance. Hypoxia in estuaries has been linked to depressed survival of larval fish, mortality of certain benthic invertebrates used as fish prey, and loss of habitat for mobile species of fish such as cod that require high oxygen availability. Hypoxia and anoxia represent a growing problem for many estuaries and coastal marine waters, such as the Chesapeake Bay, the Baltic Sea, the Black Sea, the Pamlico Estuary, Long Island Sound, the North Sea, and the Gulf of Mexico by the mouth of the Mississippi River.

Overall population sizes and biomass of fish usually increase with nutrient overenrichment, which is sometimes regarded as a beneficial effect in early to midstages of eutrophication. However, dominance shifts from species such as lake trout to cyprinids, bullheads (*Ictalurus* spp.), and other coarse fish that can tolerate low oxygen concentrations (Fig. 10). In lakes with well-developed littoral zones of rooted aquatic vegetation, high predation pressure from piscivorous fish such as largemouth bass (*Micropterus salmoides*) or pike (e.g., *Esox lucius*) maintains low biomass of cyprinid fish and, thus, low predation pressure on large-bodied zooplankton. These large zooplankton, in turn, control phytoplankton biomass through strong grazing pressure, so that there is high visibility for visually feeding piscivorous fish and abundant light for macrophyte growth.

As eutrophication progresses, the littoral-zone macrophytes disappear and the carrying capacity of the lake for piscivorous fish is reduced. Thus, (200-) planktivorous fish are freed from high predation. Their larvae tend to selectively feed on the largest herbivorous zooplankton species (based on the size-efficiency hypothesis of Brooks and Dodson), causing an overall reduction in herbivore size. Smaller herbivores cannot exert enough grazing pressure to control blooms of cyanobacteria and other noxious algae, which proliferate in eutrophic lakes and lower rivers in the absence of the large-bodied zooplankton. Turbidity increases from higher cyprinid feeding activities and from loss of the littoral-zone "filtering" effect of the macrophytes, further impairing visual predation by remaining piscivorous fish. Photosynthetic activity from the high algal
biorichness can elevate the pH to levels that adversely affect gill function in sensitive fish species.

Similar impacts on fish populations from loss of desirable littoral zone species have been documented in estuarine and coastal waters. For example, along the Swedish coast of the Baltic Sea, excessive nutrient enrichment has been related to increases in nuisance cyanobacteria and other filamentous species, as mentioned, and a decrease in formerly dominant Fucus vesiculosus (Phaeophyceae), probably because of reduced light availability. This seaweed had provided critical habitat for herring spawns and the shift to dominance by filamentous macroalgae led to decreased egg hatch in the herring populations.

Although aquatic birds and other vertebrates can move among aquatic environments with relative independence, some general effects of eutrophication on these macrofauna also have been described. Increased macrophyte vegetation under moderate nutrient enrichment in mesotrophic systems has been linked to increased numbers of herbivorous waterfowl such as moorhen (Gallinula chloropus) and whooper swan (Cygnus cygnus). Some piscivorous birds such as grebes and herons have also increased. As eutrophication progresses, however, bird species may decline following undesirable changes in food and habitat. For example, pochards (Aythya ferina) decreased on Lake Constance as their main food supply, the macroalgae Chara, declined under nutrient enrichment. General macrophyte habitat loss under nutrient overenrichment has also been linked to the gradual disappearance of many waterfowl such as black and mute swans (Cygnus atratus, C. olor strepera), Canada geese (Branta canadensis), coots (Fulica atra), teal (Anas crecca), and gadwells (Anas strepera). Sensitive life history stages of amphibians (for example, frog eggs) have been killed in increasing hypoxic events within littoral zones of eutrophic lakes.

III. OLTROPHICATION—REVERSING THE IMPACTS OF EUTROPHICATION

It is possible to reverse nutrient loading impacts, at least to some extent, by reducing the nutrient inputs. This phenomenon can occur naturally when, for example, a major storm such as a hurricane causes high flooding or sedimentation that effectively re-routes a nutrient-rich tributary away from a receiving lake or estuary (such as an oxbow lake that is cut off from the main river); when natural flooding destroys a dam and eliminates a run-of-river impoundment; or when a raised bog system becomes isolated from nutrient-rich stream and groundwater sources. As nutrient loading declines, species diversity generally increases while the system production decreases. In embrotophic bog systems, there is also a shift over time to more acid-tolerant species, as the system's sole source of new water is low-pH precipitation.

Human influences are more pervasive than the natural forces that can contribute to oligotrophication. Cultural eutrophication is an acceleration of a long-term, natural process. Resilience, defined as the rate of recovery to the predisturbance state, depends on the initial status of the system in the natural eutrophication process and on the degree of nutrient loading sustained. Ecosystem resilience is generally considered to increase with increased nutrient loading rate and to decrease with increasing food chain length. Recent analysis by Cottingham and Carpenter suggested a modification of this relationship for pelagic food webs of north temperate lakes. In that analysis, planktivore-dominated (short-length) food webs were more resilient at baseline P loading rates of 0.1 to 1.0 μg/L/day. Piscivore-dominated (long-length) food webs were more resilient at high baseline P loading rates (2.0 μg/L/day), apparently because the additional nutrients were incorporated into the biota more rapidly.

Eutrophic systems, dominated by "generalist or opportunistic" species that are insensitive to the adverse impacts from nutrient overenrichment, are considered to be relatively resistant to further change or stress as mentioned. Moreover, the adverse impacts of cultural eutrophication in such systems can be partially reversed in a relatively short period of time (several years). Less nutrient enriched systems (for example, early phases of moderate nutrient enrichment or mesotrophy) have more specialized species, more opportunity for biotic adjustment of elemental cycles, and tighter coupling among element cycles. The diverse communities of such systems, comprised of more sensitive species, are relatively sensitive to further stress imposed by nutrient enrichment under accelerated eutrophication; and reversal or "recovery" to a "pristine" oligotrophic state is difficult to accomplish.

The degree of "restoration" success also depends on certain physical features of the system, especially mean depth and flushing rate. Aquatic ecosystems tend to retain most nutrients from loading events in the bottom sediments. In deep lakes, most of the nutrient inputs
from the previous years are unavailable to phytoplankton of the next growing season because the lower water column remains permanently stratified and, thus, isolated from the upper water column where most of the viable phytoplankton occur. In shallow systems, wind and internal currents mix the water column and superficial sediments completely and frequently over an annual cycle, so that some portion of the nutrients from the relatively rich bottom waters and sediments repeatedly becomes available for phytoplankton growth. Reservoirs, rivers, well-flushed estuaries and wave-swept marine coastal waters are usually less sensitive to nutrient loading and more easily ‘reversed’ in the eutrophication process than lakes or poorly flushed coastal lagoons with long water exchange times (on the order of months to years) because the latter systems cannot flush the nutrient-laden water through and ‘self-cleanse.’

As other, more practical considerations, the extent to which the acceleration of the eutrophication process can be reversed would be expected to depend on the feature of the aquatic ecosystem that is targeted for improvement. Nutrient reductions would exert the most direct effects on plant communities such as freshwater/estuarine phytoplankton or estuarine/coastal macroalgae. Thus, a goal of reduced incidence of algal blooms may be more rapidly achieved than that of improved fish communities with growth that is indirectly rather than directly affected by the nutrient inputs. The economic feasibility of controls that can be exerted on anthropogenic nutrient sources is also important. Pragmatically, the highest prognosis for success would be expected for natural waters that are affected mostly by sewage and other point (pipe) source nutrient dischargers, because they are much easier to control than nonpoint (diffuse) sources.

One of the most famous early reports of successful reversal of cultural eutrophication involved removing sewage discharges from Lake Washington within metropolitan Seattle, Washington, in the United States. This large, deep lake (128 km², maximum depth 59 m, mean depth 18 m) historically had shown water quality degradation in response to sewage inputs. In 1922 a diversion was created to carry the raw sewage from 30 outfalls away from the lake (into nearby Puget Sound). Algal blooms and fish kills soon abated. However, in 1930 sewage effluents began to be discharged into the lake from treatment plants in outlying communities, and noxious cyanobacteria blooms and hypoxia again increased. About 76 million liters of sewage without inorganic nutrient removal were discharged daily into the lake by 1962. Nearly a decade of effort by a courageous limnologist, Dr. T. Edmonson, led the city to support zero discharge of sewage into the lake by 1968. By 1970 the lake’s phytoplankton growth had decreased to levels that had not been seen since the early 1950s, and the improvements in water quality and aesthetics were heralded by the citizenry as a ‘rapid and remarkable’ recovery. This recovery was aided by the fact that the lake is relatively deep and that the major nutrient sources to be controlled were sewage pipes. It is unlikely that the degree of recovery reversed the water quality and aquatic communities to a circa 1930, more pristine status. However, the partial recovery (partial oligotrophication) represented a major improvement.

Other partial reversals of cultural eutrophication have been reported worldwide. In freshwaters they mostly have been achieved by targeting P reductions. In estuaries, both P and N have been reduced or ‘co-managed’ for best results. Studies in north temperate estuaries by Fisher, Chesterikoff, and colleagues indicate that if only P, but not N, is removed from sewage inputs to upstream fresh waters, the P removal can actually exacerbate N-related eutrophication problems in downstream estuaries. The freshwater P reductions decrease riverine algal growth that, if present, would also have removed a substantial portion of the N, in the sewage before it reached the estuary. Soluble nitrate, in particular, is transported downstream at higher concentrations than if freshwater algal blooms had been available to consume it, and the increased N is thus available to stimulate higher phytoplankton growth in the receiving estuary.

In large lakes, partial reversals can achieve highly desirable results. For example, the degradation of fish communities in Lake Erie reached its most extreme level in the 1960s from a combination of eutrophication, overexploitation of fishery resources, extensive habitat modification, and other pollution. Beginning in the 1970s, fishery management strategies and pollution abatement programs contributed to a dramatic reversal. Lake Erie walleye fisheries rebounded to world-class status, and point-source P loading significantly declined, especially after sewage treatment was improved at the major point source discharger to the west basin of the Lake (the Detroit metropolitan wastewater treatment plant) and after mandated use of detergents without phosphorus. The P reductions effected a dramatic decrease in the abundance of nuisance phytoplankton species and of zooplankton biomass, as well as a decline in the abundance of pollution-tolerant zooplankton and an overall shift in macroinvertebrates to more pollution-intolerant taxa. Similarly, in the Bay of Quinte on Lake Ontario, P loading reductions after 1977 led to a decline...
in the abundance and biomass of oligochaete worms, sphaeroid mollusks, isoped crustacea, and some chironomids. Dominance in both chironomid and oligochaete conditions shifted to species less tolerant of eutrophic conditions.

Nutrient reductions have also led to success stories in estuaries and coastal lagoons. For example, industrial point source nutrient reductions to the Seto Inland Sea in Japan during the 1980s promoted a noticeable decline in the frequency and magnitude of toxic dinoflagellate blooms. Nutrient loadings to Cockburn Sound, Australia, from industrial point sources, and reduction in nutrient loadings to Chesapeake Bay from sewage point sources, decreased phytoplankton blooms and promoted an increase in seagrass meadow habitat. Sewage discharges to the shallow estuary, Mumford Cove, in Connecticut (United States) were rerouted to another waterway in the late 1980s, and within two years massive nuisance blooms of the macroalgae, Ulva lactuca, from industrial point sources, decreased phytoplankton blooms and promoted an increase in seagrass meadow habitat. Sewage discharges to the shallow estuary, Mumford Cove, in Connecticut (United States) were rerouted to another waterway in the late 1980s, and within two years massive nuisance blooms of the macroalgae, Ulva lactuca, were eliminated. Thus, partial "oligotrophication" from removal of sewage can have fairly rapid, positive results even in shallow systems where the sediments could provide some degree of nutrient replenishment to the overlying water.

From an overall ecosystem standpoint, the extent to which aquatic habitats can be "fully reversed" in the cultural eutrophication process depends on a more complex "endpoint" than variables such as reductions in nuisance algal growth, recovery of beneficial macrophyte beds, or increases in desirable fish species. The full range of chronic impacts from variables that frequently accompany nutrient enrichment are poorly understood. For example, scientists only recently determined that low-level water-column nitrate enrichment could inhibit the growth of certain sensitive seagrasses as a direct, subtle, and potentially serious physiological effect. Scientists only recently reported, as well, that nutrients can act to indirectly stimulate toxic, animal-like organisms such as Pfiesteria, mediated through stimulation of algal prey that are consumed by Pfiesteria species. The National Research Council has reported that there are more than 100 different enteric pathogens in sewage including viruses, bacteria, and parasites that cause waterborne diseases in humans. The fate of many of these organisms and their impacts on aquatic life have not been examined, but available evidence indicates that some of them can survive for months to years in the bottom sediments of lakes, rivers, and estuaries. Thus, many challenges of cultural eutrophication remain to be resolved before the full extent of its impacts on aquatic ecosystems, and the success of reversing those impacts, can be evaluated.

EUTROPHICATION AND OLIGOTROPHICATION

I. A Brief History of Evolutionary Thought
II. The Universal “Tree” of Life
III. Structure of Evolutionary Biology and How It Is Studied

GLOSSARY

**evolution** Descent, with modification from one (or at most, a few) original ancestors
**evolutionary theory** A body of statements about the general laws, principles, or causes of evolution
**lateral transfer** Genetic information passed between organisms through means other than inter-breeding
**phylogenetic tree** A hypothesis for describing the history and relationships among living species.

**EVOLUTION, DESCENT WITH MODIFICATION**, is a scientific fact. Evolutionary theory is a coherent body of interconnected statements, based on reasoning and evidence, that describes the processes of branching of lineages and changes within lineages (including extinction and gene transfer). Nothing in biology makes sense unless it is studied in an evolutionary context (Dobzhansky, 1973), and all fields of biology provide insight into the processes of evolution and mechanisms of evolutionary change. Therefore, the goal of evolutionary biology is to determine patterns of ancestor-descendant relationships among organisms in time and space, understand the processes that gave rise to them, and discern how the specific attributes of organisms originated and changed through time.

I. A BRIEF HISTORY OF EVOLUTIONARY THOUGHT

The development of evolutionary theory to date can be characterized by four major periods of expansion that reflect increasingly sophisticated means of documenting and quantifying natural variation at the molecular, cellular, and organismal level. The most significant development in evolutionary theory occurred between 1859 and 1930, the Darwinian period. The most significant insight of this time was recognition of the common ancestry of organisms and the force of natural selection. The next period of expansion in evolutionary thought occurred between 1930 and 1960 when Darwinian theory was reconciled with modern genetics, systematics, and paleontology. The current period of expansion in evolutionary biology, 1960 to the present, began when Lewontin and Hubby discovered the enormous amount of natural variation at the protein and nucleotide level. Currently, the molecular revolution has refocused evolutionary studies on decoding the genetic ciphers that explain evolution. The most fundamental concept in evolutionary biology, the concept
that all organisms can be divided into discrete species, is being challenged as are long-held notions about adaptation and the relationships among species. The current tree of life divides organisms into three kingdoms, the Eukarya, the Archaea, and the Bacteria.

This chapter is organized into two sections. The first section outlines the periods of expansion of evolutionary thought; the second section outlines the structure of evolutionary biology, explains how evolution is studied, and discusses recent empirical works that highlight new findings.

A. Darwinian Evolution: A Paradigm Shift in Evolutionary Thought

The word evolution is derived from the Latin word evolutio, or "unrolling." Prior to Darwin, classical thought argued that God created all species according to a chain of being or Scala Naturae. The chain of being was an expression of God's design, all objects were perfect, permanent, and unchanging; no new forms of life could have arisen or become extinct since the time of Creation. Therefore, the role of natural science was to catalog God's creations to make manifest His wisdom. Based on this view, Linnaeus established a universal framework for classifying similar species into similar genera that were thought to reflect God's design but that did not imply any genealogical connectedness. These ideas culminated in the most significant pre-Darwinian theory of evolution, put forth by Jean Baptiste Lamarck (1744–1829). Lamarck proposed that organisms evolved through adaptation to the physical environment. He introduced the theory of "organic progression" in which species originated continually via independent events of spontaneous generation and subsequently evolved "up" the scale of nature (Fig. 1a). Lamarck envisioned two hierarchical chains of life, one for plants and one for animals, and a world where extinction was not possible. Lamarck viewed changes in organisms to result from the use and disuse of organs and that these acquired characteristics were then passed to descendants. Extinction was not possible and, therefore, species identified from fossils were still present, although modified, through adaptation.

Charles Darwin (1809–1882) founded the current field of evolution. His most important contribution to the theory of evolution was the concept that all species diverged from a common ancestor and that natural selection is the mechanism driving speciation. Prior to Darwin, natural scientists accepted the idea that species struggle against one another for existence. Darwin's experience as a naturalist and the writings of Malthus, "Essay of Population Growth" (1798), helped him see that individuals, not species, struggle for life. Malthus's essay argued that the rate of human population growth was greater than the rate of the increase of food. Therefore, if reproduction is untethered, famine would drive animal populations to extinction. The realization that individuals with superior characteristics would live to reproduce, while individuals of the same species with inferior characteristics would not, triggered Darwin's belief in evolution. The struggle for existence, that Darwin believed resulted in the differential reproduction of individuals, is defined as natural selection (Fig. 1b).

B. The Synthetic Theory of Evolution

By the 1870s most scientists accepted the theory of evolution by common descent but, for at least 60 years after the publication of The Origin of Species, there was no consensus that natural selection was the mechanism by which evolution was achieved. The next period of expansion in evolutionary thought occurred in the 1930s and 1940s, when contributions of geneticists, systematists, and paleontologists reconciled Darwinian theory with the facts of genetics (Mayr and Provine, 1980). A modern understanding of genetics, together with the mathematical theory of population genetics by R. A. Fisher (1890–1962), J. B. S. Haldane (1892–1964), and Sewall Wright (1889–1988), demonstrated that mutation and natural selection were causes of adaptive evolution. The synthesis of studies in taxonomy and genetic principles built by E. Mayr (b. 1904) and G. L. Stebbins (b. 1906) provided evidence that evolution occurred gradually. The integration of paleontology with population genetics by G. G. Simpson (1902–1984) demonstrated that the synthetic theory of evolution was fully consistent with the fossil record. Alternative theories of the mechanisms of evolutionary change that had been formulated since Darwin but prior to the evolutionary synthesis, such as Neolamarckism and the view that biological systems were creative and purposeful, were demonstrated to be inconsistent with the fossil record. Therefore, the major achievement of the evolutionary synthesis was to fully integrate genetics and Darwinian evolution and to argue that the major features of evolution could be accounted for by within species processes, such as mutation, recombination, and natural selection (Futuyma, 1998).
FIGURE 1 Proposed trees of ancestor-descendant relationships visualized by Lamark (A) and Darwin (B). (A) Jean Baptiste Lamark proposed that organisms originated spontaneously, continuously and evolved "up" a chain of natural being. (B) Darwin proposed that all species evolved from a common ancestor through the mechanism of natural selection (from Futuyma, 1998).

C. The Discovery of Protein and Nucleotide Diversity

Two schools of thought emerged during the synthetic period: the selectionist school from genetics and the mathematical theory of population genetics, and the adaptionist school from paleontology and systematics. The selectionist view is that there is no limit to an organism's variability and hence ability to evolve. Furthermore, all aspects and characteristics of organisms are variable and able to change rapidly. No qualitatively new phenomena results from increased organismal complexity and adaptations reflect the sum of infinitely variable genotypes. In contrast, the adaptionist school put forth the concept of "Bauplan," or the view that groups of organisms represent broad schemes of organization and that variations among groups reflect some degree of functional and developmental constraint. In its most extreme, the adaptionist school views organisms as relatively static and only able to change over long periods of time after populations of species have been isolated.

In the early 1960s, evolutionary population genetics became the central discipline of the study evolutionary processes. The most important contribution made during that period was the discovery of the vast amount of unexplained nucleotide and protein diversity and the subsequent explosion of mathematical theory to explain the role of mutation, drift and natural selection in the evolution of populations. The resulting, deepened understanding of the molecular basis of life and genetics revealed those questions that needed to be answered to reconcile the theory of evolutionary population genetics with concepts of speciation that are based on shared patterns of organismal organization and design.

D. The Molecular Revolution and Current Evolutionary Thought

The foundation of evolution, descent with modification from a common ancestor, as stated by Darwin, remains unchanged. The molecular revolution, however, continues to transform our perspective on evolutionary thought by providing molecular tools to dissect the pathways by which characters and organisms are modified and molecular tools to probe the mechanisms by which molecules, genes, and genomic architecture interact. The unfolding complexity of these genetic pathways continues to reveal an increasing number of insights that are both exciting as well as disturbing to some. One of these is the deep genetic similarity between what are otherwise very different organisms, for example, houseflies and humans. We now know that a substantial part of genetic and biological innovation is the result of the simple mechanism of gene duplication in which genes are subsequently coopted for new functions. Furthermore, the chimeric aspect of genomes shows that organisms from the archaean lineages (the methanogens or methane-producing bacteria and bacteria that live in extreme environments), bacterial lineages (all remaining single cell organisms), and eukaryote lineages (all multicellular organisms) all contain genes
from multiple sources that are likely to have been obtained by the process of lateral transfer, not interbreeding (vertical transfer) or even de novo (Fig. 2). In fact, the lateral transfer of genetic material is so extensive that some investigators no longer consider the Archeae and Eubacteria discrete or closed systems of organization but recognize them as fluid and reisulated biological systems (Doolittle, 1999).

**FIGURE 2** (a) The three kingdoms of living organisms. The origin of the Eukaryotes, all multicellular organisms, is thought to lie somewhere between the Archeabacteria (methane-producing bacteria and bacteria living in extreme environments) and the Eubacteria (all remaining single-celled organisms). Lateral transfer (b) of genetic information among all three lineages may be extensive and its implications a matter of active debate (from BioEssays 21.2, W. Martin, © 1999. Reproduced by permission of Wiley-Liss, Inc., a subsidiary of John Wiley & Sons, Inc.).
One effect of this more pluralistic view of organisms and the complexity of genetic systems revealed through the molecular revolution has been to refocus evolutionary thinking from the inheritance of fixed characters to the inheritance of systems of organization and control. Evidence for this perspective comes from integrative studies of the fossil record and molecular developmental biology. For example, current evidence from paleontology shows that by the end of the Ediacaran, 520 Ma, all of the major clades of animals, or “stem” groups of animals, had diverged, and since that time, only one of group of organisms, the Vendobionta (preserved as impressions, casts and molds; the status of this group is controversial), has gone extinct (Fig. 3): Divergence of the Bilateria (organisms with bilateral symmetry, i.e., the Chordata and Echinodermata; the Mollusca, Annelida, Platyhelminthes, and Brachiopoda; the Arthropoda, Nematoda, and Priapula) from the sponges, cnidarians, and ctenophores resulted in all of the animal taxa recognized today. Molecular evidence shows that early-diverging Bilateria taxa display both ancestral and derived characters that include similar gene content, development, and morphology (Knoll and Carroll, 1999). All bilaterians are characterized by a modern body plan (rostral-caudal body axis) and an extensive cluster of homeobox genes (Hox genes encode a sequence of 60 amino acids that bind to DNA and control its expression) that control interacting networks of developmental regulators and key structural genes (Knoll and Carroll, 1999). The different degrees and types of organization that characterize the modern descendants of these groups are the result of a mosaic of genetic and morphological phenotypes whose components evolve at different rates.

Understanding the developmental basis of organismal variation provides insight into the potential for evolutionary change, as well as its pattern. For example, the two major groups of bilaterians—the Protosomes (illustrated primarily in Drosophila melanogaster) and the Deuterostomes (illustrated primarily by vertebrates)—share a common genetic regulatory repertoire. This means that the common ancestor of the arthropods and chordates would have had all the genes that they share, as well as all of the morphological characters that the shared genes regulate: photoreception organs, appendages, a heart, and the propensity for body seg-

---

**FIGURE 3** Animal diversity across the Phanerozoic–Cambrian transition. By 520 Ma, all major clades of animals had diverged. All bilaterians are characterized by a rostral-caudal body plan and extensive cluster of homeobox genes. The descendants of these groups are mosaics of genetic and morphological phenotypes whose components evolve at different rates (Reprinted with permission from Knoll and Carroll, Early Animal Evolution © 1999, American Association for the Advancement of Science).
EVOLUTION, THEORY OF

mentation (Knoll and Carroll, 1999). Through the replication and multiplication of regulatory networks, such as the Hox gene complex, taxa diverged as the complexity and the hierarchy of gene interactions increased. All of the proteins that cause the differentiation of body organization, however, did not and hence were present over 530 million years ago (Marin and Baker, 1998). Therefore, periods of great diversification in evolution, such as the Cambrian explosion, record the differentiation of crown (recently evolved) groups within clades that diverged as a result of an earlier radiation of genetic regulatory systems among stem (ancestral) taxa (Knoll and Carroll, 1999).

II. THE UNIVERSAL “TREE” OF LIFE

The current phylogenetic tree, based on small subunit RNA as well as whole genome-based phylogenetic analysis, distributes species among three groups of primary relatedness or domains: the Bacteria, the Eukarya, and the Archaea. The root of the Eukarya is between the Bacteria and Archaea (Fitz-Gibbon and House, 1999). Exploring the relationships among genes, regulatory processes, and the species that are contained in them has led to the concept of a phylogeny (the evolutionary history of an organism) as a diffuse cloud of gene histories that may make it difficult to organize organisms into Linnaean systems. Therefore, one current perspective of phylogenies or the histories of lineages are as models of the change in the interbreeding probabilities between organisms and models of genetic potentialities of organisms through time (Maddison, 1997).

III. STRUCTURE OF EVOLUTIONARY BIOLOGY AND HOW IT IS STUDIED

The are two central questions in evolutionary biology: The first question asks, what is the history of life, as defined by the history of the species, their origins, and extinction, and what are the steps through organisational features evolved? The second question asks, what are the causes of the history life? While the major principles of evolutionary biology and major causes have been established, new questions are continually posed and many long-standing questions remain to be fully answered. The processes of evolution are both random and deterministic: Studies in nine subdisciplines, as well as syntheses among these, contribute to understanding evolution and its mechanisms: evolutionary ecology, behavioral evolution, evolutionary paleontology, evolutionary developmental biology, evolutionary physiology and morphology, evolutionary systematic biology, evolutionary genetics, molecular evolution, and human evolution. Research in all of these fields has accelerated in the past 20 years as the focus of evolutionary studies continues to shift.

A. Evolutionary Ecology

The most important questions in evolutionary ecology address the role the environment plays in speciation and extinction. During the synthetic period of evolution, the dominant view of speciation was that geographic barriers would develop between two populations prohibiting gene flow between them. Even though the populations might live in identical environments, they would diverge gradually as a result of the accumulation of random mutations. In contrast, however, some researchers have proposed that the barriers spawning species can also be ecological. In this case, selection, as opposed to isolation, is the factor that drives speciation. This implies that speciation is the product of an event, not a process. Both modes have received support in recent studies.

Peterson et al. defined and compared the ecological niches of birds (21 pairs), mammals (11 pairs), and butterflies (5 pairs) in an area of active speciation and population differentiation, the Isthmus of Tehuantepec. They tested the degree to which the ecological characteristics of one taxon were able to predict the geographic distribution of its putative sister taxon and vice versa. They then computed a genetic algorithm to produce a set of decision rules in ecological space (a model of the fundamental niche) that were projected onto maps to predict potential geographic distributions of the taxa. Across the 37 species pairs they found that a taxon on one side of the Isthmus could more accurately predict the distribution of its sister taxon on the opposite side of the Isthmus of Tehuantepec than the distribution of any of the other species. They concluded that because the species on each side of the Isthmus had been isolated for several million years, the sister species that evolved on each side of the barrier were the result of random genetic events but not natural selection (Peterson, Soborin, and Sanchez-Cordero, 1999).

An alternative view of the speciation process is that ecological variation, such as climate variation or differences in food resources can act as barriers, and can select for adaptation. This may result in individuals that are morphologically different and are unwilling to mate with each other even though they have never been
physically separated. The most famous example of adaptive radiation and how ecological niche can drive the evolution within a population is seen in studies of Darwin’s finches. While journeying on the Beagle, Darwin collected 14 different species of finches from the Galápagos Islands. The different species of finches showed a degree of variation in beak size, beak shape, and body size that usually characterizes differences among families of birds. Nevertheless, the entire radiation of the finches is believed to have occurred in less than 3 million years. Using microsatellites (multilocus genetic markers with high mutation rates), Petren, Grant, and Grant (1999) found that 13 of the species of Darwin’s finch that they studied were monophyletic (derived from the same common ancestor). Their many differences in phenotypic traits, including beak size and shape, body size and plumage, are derived from an ancestor with a relatively long pointed beak that is associated with an insectivorous diet. From this ancestor, ground finches evolved blunted beaks that are efficient for crushing seeds while tree finches evolved beaks that allowed greater biting strength at the tip. Furthermore, once a novel beak evolved, body size and beak size changed rapidly and allometrically (Petren et al., 1999). They concluded that divergence among the finches reflects strong selection for ecological type.

B. Behavioral Evolution

Behavior is studied at two levels: (a) the neural, hormonal, and developmental mechanisms that underlie the adaptive differences and the historical pathways leading to a current behavior and (b) the selective processes shaping behavioral evolution. When put in an evolutionary context, the importance of a behavior is measured through its effects on animal reproductive success. One particularly clear example is when the status or dominance rank of an animal that lives in a group or community correlates with the animal’s reproductive success. For example, a recent analysis of 30 years of data gathered on the chimpanzee community at the Gombe Stream Research Center, Tanzania, has shown that female chimpanzees, who are solitary foragers, do not display an obvious linear hierarchy. Female status, however, affects her reproductive performance in several ways: offspring of high-ranking females survive longer, the age at which offspring reach sexual maturity is sooner when mothers are high-ranking, and average female life span is longer among high-ranking females (Fig. 4). Furthermore, a female’s dominance correlates with age until she reaches 21 where the rank she has achieved strongly predicts her rank for the next 10 years. Understanding the effects of this kind...
of reproductive skew is important to the genetic diversity of species. When populations become small and isolated, genetic diversity of the population is likely to be reduced by the successful reproduction of a few dominant individuals (Pusey, Williams, and Goodall, 1997).

C. Evolutionary Paleontology

Paleontology addresses broadscale evolutionary patterns by tracing origins and fates of lineages and major groups, changes in characteristics and relationships of evolving lineages, and temporal variations in species diversity through the fossil record. Paleontologists, however, can only assess these changes through shifts in animal size. Hence paleontology cannot address the diversity or effects of the evolution of organismal physiology, only its pattern.

Research in evolutionary paleontology has become increasingly interdisciplinary and as a result four key, interrelated research questions have emerged: (a) What are the rules that govern biodiversity dynamics and do they apply at all temporal and spatial scales? (b) Why are major evolutionary innovations unevenly distributed in space and time? (c) How does the biosphere respond to environmental perturbations at global and region scales? (d) How have biological systems influenced the physical and chemical nature of the earth's surface, and vice versa (Jablonski, 1999)? For example, mass extinctions are not only important for the species that they eliminate, but for the evolutionary diversification and ecological restructuring that occur in their aftermath (Jablonski, 1998). Five major mass extinctions in the Mesozoan fossil record were followed by rapid recovery of global taxonomic diversity and the radiation of new or previously minor groups. In a recent study, Jablonski examined the end-Cretaceous biotic recovery patterns among marine mollusks in four geographic provinces: the U.S. Gulf Coast, northern Europe, Northern Africa, and Pakistan-northern India. Although extinction intensities and selective effects were similar in the molluskan faunas of all four areas, the regions differed in the dynamics of diversifying clades and in the proportion of local taxa and invaders in the post-extinction biotas (Jablonski, 1998). In particular, three of the four regions lacked a rapid expansion and decline of "bloom taxa," as well as proportionally fewer invaders early in the recovery phase. Applying this result—contrary to the existing paradigm where global compendia of taxa are amassed to provide broad taxonomic analyses—Jablonski showed that distinct biogeographic regions are semiautonomous in their response to environmental crises. While some investigators have proposed that the differential success of individual clades was due to intrinsic properties of the clade, Jablonski's studies show that biogeographic, environmental, and paleoecologic context are critical to any understanding how diversity changes.

D. Evolutionary Developmental Biology

Developmental, evolutionary biology reveals how changes in genetic information at the DNA level or genotype are translated into changes in organismal morphology or phenotype. For example, the molecular phylogenies of 18S ribosomal sequences show that the bilatera should be reorganized into three different clades: the Deuterostoma (chordates and echinoderms), the Lophotrochozoa (molluscs, annelids, platyhelminths, and banchiopods), and the Ecdysozoa (chelicerates, crustacea, myriapods, insects, and onychophora). The result of this reordering, however, is that early evolving groups in derived clades must have displayed both ancestral and derived characters in combination (Knoll and Carroll, 1999).

Developmental biology shows that the apparent discrepancies between molecular and morphological data are resolved when the mechanisms that regulate gene expression are understood. For example, a marked trend in arthropod evolution has been an increase in body segment and appendage diversity. Hox genes play three major roles in the evolution of arthropods: (a) the entire arthropod clade contains the same set of Hox genes that are responsible for the recent diversity in Cambrian animals, (b) the increase in segment diversity is correlated with changes in the relative domains of Hox genes, and (c) changes in the morphology of homologous appendages are correlated with changes in the array of genes that are regulated by the same Hox gene (Knoll and Carroll, 1999). Therefore, most arthropod body plans are the result of very similar complexes of Hox genes. In addition, the correlation between diversification of Hox gene expression and patterns of evolution suggest that the diversification of bilaterian body plans is primarily due to the evolution of developmental regulatory systems, not changes in the genes themselves (Knoll and Carroll, 1999).

E. Evolutionary Physiology and Morphology

Evolutionary physiology and morphology determine how biochemical, physiological, and anatomical aspects
of organisms affect their ability to adapt to new environments and ways of life. Contemporary studies focus on asking how form and function relate to each other during evolution, why some species are tolerant of broad physical ranges and others are not, and if there is more than one way for an animal to adapt to its environment. One of the most interesting discoveries of this field is that even when the fossils of ancestors are similar to their descendants, the descendant’s biochemistries may be diverse and able to adapt to almost any physiological need.

For example, the macroevolutionary importance of plant chemistry on herbivore host shifts is critical to understanding the evolution of insect-plant interactions (Becerra, 1997). Members of the New World, monophyletic genus of the beetle, *Blepharida* (Chrysomelidae: Alticinae), feed mainly on *Bursera* (Burseraceae). While plants in the *Bursera* genus produce an array of terpenes that are toxic or repellent to most herbivores, they only decrease *Blepharida* survival and growth rate. To determine the importance of plant chemistry to the phylogenetic diversification of the beetles and their feeding behaviors, Becerra (1997) constructed a dendrogram of *Bursera* species based on their chemical similarity. She found that most clades of *Bursera* include plants that are in different chemical groups suggesting that their chemical similarity is partially independent of plant phylogeny. She also found that *Blepharida* rarely shifted between chemically dissimilar plants and, in fact, subclades of *Blepharida* appear to have colonized species of plants that belonged to only one chemical group even if they shifted between hosts belonging to different subclades several times (Fig. 5). Therefore, comparison of plant phylogeny and plant chemical variation indicate a greater influence of host plant chemistry than host plant phylogeny in the evolution of the *Blepharida* and *Bursera* interaction.

**F. Evolutionary Systematic Biology**

Evolutionary biology is based on the principle that all organisms share a common history. Evolutionary systematics attempts to organize history by cataloging species, determining their genealogical or phylogenetic relationships, and classifying them into inclusive or hierarchical groups. Systematic studies prior to 1980 were largely based on morphological comparisons among taxa. Recent research, however, has reanalyzed and broadened past work using molecular tools. DNA analyses provide independent estimates of the age of phylogenetic groups while extending and revising our understanding of organismal relationships. For example, corals are Cnidarians, the sister taxa of the Bilateria, and evolved at least 600 million years ago.
ago. The scleractinian corals (reef-building corals) have a continuous fossil record from the mid-Triassic (about 160 million years ago) and support some of the world’s most diverse marine communities. Despite this detail, their skeletal variability and morphology have made it difficult to understand the relationships among coral families and suborders (Romano and Palumbi, 1996). Molecular phylogenetic analysis of mitochondrial 16S ribosomal RNA, however, has helped to clarify coral evolution and revealed that scleractinians originated 80 million years earlier than they appear in the fossil record. The mitochondrial data show a deep split in the coral lineages that predates skeleton formation and thus is invisible in the fossil record. Using a combined molecular and traditional analyses, Roman and Palumbi suggest that the scleractinian skeleton evolved repeatedly and converged during evolution. This is important because if the selective events that led to the multiple convergences in the scleractinians can be identified, we will be able to understand the selective events that led to the complex, marine ecosystems that the corals support (Romano and Palumbi, 1996).

G. Human Evolution

Evolutionary biology is studied from two different viewpoints: a conceptual view, such as theoretical population genetics, or an organismal view, such as Homo. Anthropologists and biologists studying human evolution use the same principles, concepts, and tools as other biologists. Some investigators focus on the genetic processes that affect contemporary human populations, such as human genetics and medical genetics. Other investigators draw information from evolutionary systematics, paleontology, genetics, ecology, and animal behavior. One example of an organismal study that taps information from many fields of anthropological research explores the hypothesis that cooking has played a critical role in the evolution of human social systems. Using evidence from the fossil record, Wrangham et al. (1999) propose that cooking first appeared among hominoids 1.9 million years ago. They propose that the observed increase in female body mass was the effect of increased food energy that is released when foods are cooked, and that smaller tooth size reflected the reduced digestive effort that results when foods are partially broken down before eating. Furthermore, foods that were cooked and made more digestible resulted in increased nutrient accessibility. Food that was gathered, accumulated and stored until cooked became a valuable and defensible resource that changed the economics hominoid foraging. Females fitness, limited by access to energetic resources, could be enhanced if the females formed bonds with food-guards or males willing to defend them. Females could have competed for the best food-guards through extended sexual attractiveness. Wrangham et al. (1999) suggest that cooking was responsible for the evolution of human social systems where pair-bonds are embedded within multimale and multifemale communities and are supported by strong, mutual, and frequently competing sexual conflicts (Wrangham, Jones, Laden, Pilbeam, and Conklin-Brittain, 1999).

H. Evolutionary Genetics

Evolutionary genetics, which includes population genetics, uses both molecular and classical genetic methods to understand the origin and effects of mutation and recombination. It employs empirical studies and theoretical methods to uncover the roles of genetic drift, gene flow, and natural selection to predict and interpret evolutionary change. Perhaps the most important finding in this field is the large amount of genetic variation in protein phenotypes that seem to have no immediate selective value. Furthermore, recombinant DNA technology has revealed that there are large amounts of previously undetected polymorphism at the nucleotide level that do not affect changes in amino acid sequence. Constancy in protein sequence in the face of nucleotide polymorphism shows that selection is acting directly at the DNA level preventing the evolution of deleterious proteins (Kreitman, 1983).

I. Molecular Evolution

Springing directly from the molecular revolution, molecular evolution focuses on causes of evolutionary change at the level of the gene, protein, and genome. It takes the position that evolution occurs on diverse scales of time. For example, antibodies recognize and distinguish among specific molecular patterns of antigens. Because antigens are structurally diverse, the repertoire of antibodies must be large enough to protect organisms from a wide range of pathogens and toxic agents. This diversity is achieved through three, germ-line, gene segments, which combine to generate antibody types. These are further altered through somatic mutation (not inherited) that increases the antigen’s affinity and specificity as the immune response proceeds (French, Laskov, and Scharff, 1989; Tonegawa, 1983).

Wedemayer et al. (1997) compared the structure of the germline Fab fragments, and its complex with hapten, to the corresponding crystal structure of the affinity
matured antibody 48G7. Combinatorial association between CDR1 and CDR2 regions in the primary antibody repertoire allows antibody combining sites to be more diverse than the flanking, germine-encoded sites. However, rather than a few large changes occurring at the active site, antibody maturation depends on small additive changes, many of which result from somatic mutations, to reconfigure the active site. By mapping structural changes due to nine amino acids, Wedemayer et al. (1997) showed that somatic mutations resulted in 30,000 times higher affinity for hapten. None of these, however, directly contacted the hapten; only two were within 5.5 Å of the hapten binding site and all others were at least 10 Å away. Instead, the mutations resulted in reorganized hydrogen bonding networks on the molecule’s surface, shifting the backbone conformation of the antibody protein.

GLOSSARY

complementary conservation Application of a range of conservation techniques (including ex situ and in situ) to conserve the target taxon, one technique acting as a backup to another. The degree of emphasis placed on each technique depends on the conservation aims, the type of species being conserved, the resources available, and whether the species has utilization potential.

conservation Maintenance of the diversity of living organisms, their habitats, and the interrelationships among organisms and their environment.

econeography Analysis of a species’ ecological, geographical, and taxonomic characteristics to assist in the formulation of collection and conservation priorities.

effective population size (Ne) Number of conserved individuals that would undergo the same amount of random genetic drift as the actual population.

ex situ conservation Conservation of the components of biological diversity outside their natural habitats.

gene pool The total genetic diversity found within an individual species or species group.

genetic erosion Loss of genetic diversity from a species, often caused by anthropogenic factors.

in situ conservation Conservation of ecosystems and natural habitats and the maintenance and recovery of viable populations of species in their natural surroundings and, in the case of domesticates or cultivated species, in the surroundings where they have developed their distinctive properties.

keystone species Usually the dominant species within a habitat that tend to define it physiognomically and ecologically, for example, by determining nutrient and water cycling.

target taxon Species or species group that the conservation action is focused upon.

EX SITU AND IN SITU CONSERVATION approaches focus on the protection of species outside their natural habitats or in their natural surroundings, respectively. This article outlines the basic concepts of biodiversity conservation by discussing why conservation is needed, the major threats to animal and plant species, and how we can set about ensuring that the diversity of living organisms is maintained at the ecosystem, species, and genetic levels. The importance to humankind of the
EX SITU, IN SITU CONSERVATION

The Convention on Biological Diversity is also considered. A simple model for biodiversity conservation is proposed and discussed. This involves the selection of target taxa for conservation, gene pool concepts, ecogeographic surveys, preliminary survey missions, clarification of conservation objectives and field exploration, the two basic conservation strategies (ex situ and in situ) and the range of conservation techniques, and ways that conservation is often linked to some form of utilization. Finally, the critical need of adopting a sustainable and integrated approach to conservation is emphasized, so that we can endeavor to pass to future generations the levels of biodiversity that we inherited from our forebears.

I. INTRODUCTION

The conservation of biodiversity is of critical importance now, because that very diversity is under threat of extinction and erosion, but also because it can be of direct and indirect benefit to humankind. Biodiversity benefits humans through the exploitation of animals and plants in agriculture and horticulture, the development of medicinal drugs, and the pivotal roles played by species in the functioning of all natural ecosystems. Biodiversity is also valuable for ethical, aesthetic, and recreational reasons. The fundamental importance of these issues to humankind was paramount at the United Nations Conference on the Environment and Development (UNCED) held in Rio de Janeiro, Brazil, in 1992. The Convention on Biological Diversity (CBD), which has subsequently been ratified by 175 countries (as of January, 1999), has as its objectives the conservation of biological diversity, the sustainable use of its components and the fair and equitable sharing of the benefits arising out of the utilisation of genetic resources. (Article 1: Objectives, Convention on Biological Diversity, 1992)

II. WHY DOES BIODIVERSITY NEED CONSERVATION?

Estimates of the total number of species in the world vary, and it is difficult to estimate rates of species extinction, but the consensus view summarized by Lugo (1988) was that 15–20% of all species could become extinct by the turn of the century. It is even more difficult, if not impossible, to estimate precise levels of genetic erosion, that is, the loss of genetic diversity from extant species. However, the loss of genetic diversity must always be faster than the loss of species because there will be some genetic erosion from the species that remain extant. Loss of any genetic diversity means that the affected plants or animals will not be able to adapt to changing conditions quite so readily; for example, potato cultivars with a narrow genetic base were unable to withstand the infection of late potato blight (Phytophthora infestans) in the late 1860s in Ireland, the crop was devastated, and millions were forced to emigrate or starve. Although genetic erosion cannot be quantified accurately, it seems likely that virtually all species are currently suffering loss of genetic variation to varying degrees. Therefore, using Lugo’s figures as a starting point, it may be estimated that 25–35% of plant and animal genetic diversity could possibly be lost over the 12 year period leading up to the year 2000 (Maxted et al., 1997a).

Of course loss of biodiversity also occurs at other levels than species, for habitats and ecological communities can also be degraded or destroyed. For example, virtually all of the natural grasslands in the United States have been lost since 1942 (Spellerberg, 1996), over 90% of natural wetlands in New Zealand have been lost since European settlement, and Fernside (1990) estimated that world forest loss was proceeding at 20,000 km² per year. In a similar study, FAO and UNEP (1991) found that annual rates of forest loss had increased from 113,000 km² to 169,000 km² per year between 1980 and 1990 in 76 countries.

It is important to realize, however, that both species extinction and genetic erosion can be natural events, just as species and genetic evolution are natural, nature is and it seems has always been dynamic. Yet the current levels of species extinction and genetic erosion are dramatically higher than the so-called background levels that existed hundreds, thousands, and millions of years ago. Humankind now has the capacity to drastically alter the world environment in ways that were not previously possible, and these anthropogenic changes are undoubtedly increasing the rates of species and genetic extinction.

III. WHAT THREATENS BIODIVERSITY?

The threat to biodiversity as a result of anthropogenic changes is not universal for all species. Some species...
are in greater danger of genetic erosion (or even of complete extinction) than others. These dangers must be evaluated carefully, so that those exposed to the highest risk can be given higher priority for conservation. However, it must also be borne in mind that levels of threat often change rapidly and unexpectedly. Thus, an area may suddenly come under the threat of industrial development, road-building, or logging. Diamond (1989), Gomez-Campo et al. (1992), WCMC (1992), and WRI et al. (1992) discuss in detail the kind of events that may lead to genetic erosion. These may be broadly grouped under the general headings of

- destruction, degradation, and fragmentation of natural habitats;
- overexploitation and incidental take;
- introduction of exotic species that compete with, prey on, or hybridize with native species;
- human socioeconomic change and upheaval;
- changes in agricultural practices and land use; and
- calamities, both natural and man-made.

It is valuable to establish a system by which the relative threat of genetic erosion can be assessed objectively. Guarino (1995) proposed a model for estimating the threat of genetic erosion that a taxon (wild or cultivated) faces in a particular region. The model may be used without having to visit the region involved, providing some background data are available on the taxon and the area. The model is based on scoring a number of parameters, such as the abundance of the taxon, the level of agricultural development, and the proximity and intensity of various types of human activity to the populations being studied. The higher the score, the greater the risk of genetic erosion and therefore the higher priority for in situ or ex situ conservation.

The International Union for Conservation of Nature and Natural Resources (IUCN, now known as the World Conservation Union) has developed a system of categories of conservation status, which is based on detailed knowledge of the population dynamics and genetics of the species concerned, the so-called IUCN Red Data List Categories (IUCN, 1994) (Fig. 1). Table 1 shows how some of these categories are determined. Using these categories, for example, a “critical” species would be assigned higher conservation priority than a “vulnerable” species. However, IUCN has tended to focus their attention almost exclusively on species extinction rather than genetic erosion within individual gene pools, and the latter may be of equal importance in terms of loss of biodiversity.
### IV. WHAT IS BIODIVERSITY CONSERVATION?

Spellerberg and Hardes (1992) stated that biodiversity conservation aims to "maintain the diversity of living organisms, their habitats and the interrelationships between organisms and their environment." But how is this to be achieved?

Conservationists must clearly define and understand the processes involved, and then attempt to develop practical techniques to achieve this objective. When undertaking a particular conservation exercise, a conservationist must use his or her knowledge of genetics, ecology, geography, taxonomy, and many other disciplines to understand and manage the biodiversity that is being conserved.

It is important to stress that conservation is not just about individual plant and animal species, but includes all aspects of biodiversity from ecosystems (a community of organisms and its abiotic environment), through communities (a collection of species found in a common environment or habitat), species, and populations, to genetic diversity within species. In recent years there has been a differentiation between conservation at the ecosystem and at the genetic levels, and these may be referred to as ecological and genetic conservation, respectively.

Ecological conservation focuses on the conservation of whole communities, although the survival of individuals and the extinction of particular species are a major concern, both are viewed in the larger context of overall community health. This form of whole-community conservation is exemplified by the 'Man and the Biosphere' program (UNESCO, 1996), which established a network of biosphere reserves representing distinct biomes and ecosystems throughout the world. The clear emphasis was on conservation of ecosystems: this program believed that individual species should be conserved as a component of ecosystems rather than on a species-by-species basis.

Genetic conservation focuses more explicitly on particular taxa and attempts to conserve the full range of genetic (allelic) variation within those taxa. The aim of this form of conservation is often utilitarian, for genetic diversity conservation is often linked intimately to human utilization. However, Maxted et al. (1997b) stressed the following points: first, species usefulness does not have to be defined in the strictest utilitarian sense, because plants and animals considered of aesthetic value are equally worthy of receiving human value as those of immediate use to plant or animal breeders; and second, in many cases individual species cannot be conserved without conserving the communities in which they naturally occur. So the distinction between the two basic forms of conservation is in practice blurred and may be viewed as artificial and of limited semantic importance, because the conservation of ecosystems and species are intimately linked. Just as it is difficult to focus conservation effort on the generality of the entire ecosystem, in practice conservationists need to focus on something more tangible that can be monitored and managed, even if only as an exemplar for the ecosystem as a whole.

So to undertake effective conservation, species inter-
actions must be understood as far as possible. Even if the conservation target is a population of a single species, no populations survive in isolation. They exist within a community or ecosystem and interact with other species and the abiotic environment. Obvious examples of interactions include pollinators, seed dispersers, microbial symbionts, herbivores (whether natural or introduced by humans), predators, and pathogens. Thus, even when applying genetic in situ conservation, the maintenance of genetic diversity will have to be considered within the context of whole-ecosystem conservation.

The so-called keystone species are important in this context, for these species contribute significantly to the structure of a community or its processes; they are the dominant species. The removal of a keystone species renders other members of a community vulnerable to extinction. Tropical trees that produce a rich food resource in the form of fruit or seeds, for example, can be considered keystone species, as they provide a vital food source for a diverse array of mammals and birds. Generally keystone species play an important part in interactions between different trophic levels, whether they are predators, herbivores, mutualists such as pollinators, or decomposers. So when considering the conservation of any particular species within an ecosystem, one must identify the inherent interactions and ensure their maintenance if the conservation project is to be successful and sustainable.

V. METHODS OF CONSERVATION

There is a need to develop appropriate methodologies for biodiversity conservation, particularly in the tropics. The tropical regions of the world have the highest levels of biodiversity, but their fauna and flora are the least well known and are most under threat. Also, tropical nations have few conservationists and often they are insufficiently trained; furthermore, the resources available for conservation activities are relatively limited. To address these issues, the CBD asks nations to:

Promote and encourage research which contributes to the conservation and sustainable use of biological diversity, particularly in developing countries. (Article 12; CBD, 1992)

Improve capability for determining scientific research priorities via transparent, “user friendly” risk evaluation methodologies. (Chapter 35 of Agenda 21; CBD, 1992)

Maxted et al. (1997b) responded to this requirement—to clarify and enhance the methodologies and research programs that currently enable scientists to classify, conserve, manage, and utilize biodiversity—by proposing a model for plant and animal genetic diversity conservation (Fig. 2). The raw materials of genetic conservation are genes within gene pools, which represent the total diversity of genetic material of the particular taxon being conserved. The product of the gene pool (seeds, ovules, etc.) is either preserved or utilized as genetic diversity. The processes that link the raw matter and the utilized gene pool represent genetic conservation.

A. Selection of Target Taxa

Conservation activities will always be limited by the financial, temporal, and technical resources available. Conservation of ecosystems or species has a cost and
the effort expended is directly related to how much society values that species and is therefore willing to pay. It is impossible to actively conserve or monitor all species, so it is important to make the most efficient and effective selection of species on which to focus conservation efforts. This choice should be objective and based on logical, scientific, and economic principles related to the perceived value of the species. Maxted et al. (1997a) discussed the sort of factors that provide a species with "value": current conservation status, potential economic use, threat of genetic erosion, genetic distinction, ecogeographic distinction, national or conservation agency priorities, biological importance, cultural importance, relative cost of conservation, conservation sustainability, and ethical and aesthetic considerations.

Rarely will one of the these factors on its own lead to a taxon being given conservation priority. More commonly, all or a range of these factors will be assessed for a particular taxon and then it will be given a certain level of national, regional, or world conservation priority. If the overall score passes a threshold level or is higher than those of competing taxa, the taxon will be conserved; it will then be either collected and conserved ex situ, an appropriate reserve will be established, or on-farm conservation will be proposed. Having listed the factors that affect the selection of target taxa in terms of value to society, those related to potential economic use will commonly be given higher comparative value, especially in economically poorer economies where income generation is of the highest priority. This anthropocentric and utilitarian view in the selection of conservation priorities may offend some conservationists, but when financial resources for conservation are, and are likely to remain, limited, and when men, women, and children are still suffering from malnutrition in many parts of the world, there appears to be no practical or ethical alternative to giving those species of most direct use to people the highest value and thus the highest conservation priority.

B. Project Commission

In practice, once taxa are selected for conservation, the actual conservation activities are necessarily preceded by some form of commission statement. This is likely to establish the objectives of the conservation, specify the target taxa and target areas, state how the material is to be utilized and where the conserved material is to be safely duplicated, and perhaps indicate which conservation techniques are to be employed. A clear, concise commission statement will help to focus subsequent conservation activities.

Who writes the commission? The commission statement may be written by those contracting the conservation or those who actually undertake the conservation work. The commission may vary in taxonomic and geographic coverage from a systematic collection program for a single species throughout its geographic range to a range of target taxa from a restricted location, for example, onion (Allium) species of Central Asia, large cat species worldwide, or chickpeas (Cicer) from the Western Tien Shen. In each case, however, a particular group of taxa from a defined geographical area must be considered to be insufficiently conserved (either in situ or ex situ), of sufficient actual or potential use, and/or endangered to warrant active conservation.

C. Ecogeographic Survey and Preliminary Survey Mission

Once the target taxon or group of taxa have been selected and delimited, the conservationist begins to amass and synthesize fundamental biological data to help formulate an appropriate conservation strategy. The synthesis and analysis of these data enables the conservationist to make vital decisions concerning, for example, which taxa to be included in the target group, where to find these taxa, which combination of ex situ and in situ conservation to use, what sampling strategy to adopt, where to store the germplasm and site the reserve or what captive breeding program would be most successful. If the basic biological data for a particular species, for example, the close lentil relative Lens orientalis, indicate that the species has been previously found on stony slopes at the edge of the Fergana valley in Uzbekistan, then further material of this species is likely to be currently found under similar constraints and is less likely to be found in different habitat types or in far distant regions.

The process of collating and analyzing geographical, ecological, and taxonomic data for use in designing conservation strategies is referred to as ecogeography and was defined by Maxted et al. (1995) as an ecological, geographical and taxonomic information gathering and synthesis process for a particular taxon. The results are predictive and can be used to assist in the formulation of collection and conservation priorities. Ecogeographic studies involve the use of large and
complex data sets obtained from the literature and from the compilation of passport data associated with herbarium specimens and germplasm accessions. These data are synthesized to produce three basic products: the database, which contains the raw data for each taxon; the conspectus, which summarizes the data for each taxon; and the report, which discusses the contents of the database and conspectus, as well as proposing appropriate conservation strategies. Ecogeographic techniques enhance the efficiency of crop relative and wild species conservation because they enable the conservationist to identify clearly the geophysical regions and ecological niches that the taxon inhabits, and so not only identify areas with high numbers of target taxa, but also areas that contain high taxonomic or genotypic diversity of taxa, uniqueness of habitat, economic or breeding importance, and so on.

If the available ecogeographic data for the target taxon are limited, the conservationist will not have sufficient background biological knowledge to formulate an effective conservation strategy. In this case it would be necessary to undertake an initial survey mission to gather the novel ecogeographic data required on which to base the actual strategy. The survey mission may be in the form of “coarse grid sampling,” which involves traveling throughout a likely target region and sampling sites at relatively wide intervals over the whole region. The precise size of the interval between sites depends on the level of environmental diversity across the region, but it may involve sampling every 1–30 km. The population samples and data collected during this mission can then be used to formulate further conservation priorities and to develop an appropriate strategy, thus providing the same result as the ecogeographic survey for groups that are better biologically understood.

D. Conservation Objectives

The products of the ecogeographic survey or survey mission provide a basis for the conservationist to formulate future conservation priorities and strategies for the target taxon. Within the target area, zones of particular interest may be identified, for example, areas with high concentrations of diverse taxa, low or very high rainfall, or high frequency of saline soils or extremes of altitude or exposure. In general, areas with very distinctive characteristics are likely to contain plants with distinct genes or genotypes. If a taxon is found throughout a particular region, then the researcher can use the ecogeographic data to positively select a series of diverse habitats to designate as reserves. If a taxon has been found at one location but not at another with similar ecogeographic conditions, then the ecogeographer may suggest that these similar locations should be searched. Within the target taxon, specific variants may be identified that warrant conservation priority, for example, species that have previously unrecognized utilization potential, populations that are particularly in danger of genetic erosion, or those that had not previously been conserved.

The conservationist must set out a clear, concise statement of the proposed conservation strategy for the target taxon and, if appropriate, prioritize actions. These may have been established in the project commission, but if not the conservationist should undertake the task. This should answer questions such as: Which populations require conservation? Can local farmers play a part in conservation activities? Do population levels require close monitoring? Should a national or international collecting team be directed to collect the priority target taxa? What conservation strategy or strategies are appropriate? What combination of conservation techniques is appropriate or is a more detailed study required before any of these questions can be answered?

E. Field Exploration

Once the conservation objectives have been clarified, whichever conservation strategy is to be applied, the ecogeographic information is used to locate and identify the general locality of the animal or plant populations that are to be conserved. The ecogeographic data will rarely be sufficiently comprehensive to precisely locate actual populations. Therefore, the preparatory element of conservation activities will be followed by field exploration, during which actual populations are located. Ideally, populations of the target taxon that contain the maximum amount of genetic diversity in the minimum number of populations will be identified, but how is this goal to be achieved? Commonly there will be too much diversity in both crops and wild species to conserve all their alleles, even if these were known then or at some future time. Thus the conservationist must attempt to conserve the range of diversity that best reflects the total genetic diversity of the species. How many animals or plants must be sampled, which specimens and what pattern of sampling is appropriate? To answer these specific questions the conservationist should know the amount of genetic variation within and between populations, local population structure, the breeding system, taxonomy and ecogeographic requirements of the target taxon, and many other biologi-
cal details. Some of this information will be supplied following the ecogeographic survey, but some will remain unavailable. Therefore, the practice of field exploration will be modified depending on the biological information on the target taxon and target area that is available.

For a botanical project, the field botanist should select populations if they are found on the periphery of the target taxon’s distribution or those that contain morphological or ecological variants. Atypical populations or those growing under atypical conditions may possess genes or alleles that are unknown or extremely rare in the target taxon’s center of diversity, and this material possibly contains genetic variation that is of special use to breeders (e.g., disease or pest resistance or adaptation to soil or climate that is unknown in the crop itself).

F. Conservation Strategies

There are two basic conservation strategies, each composed of various techniques, that the conservationist can adopt to conserve genetic diversity once it has been located. The two strategies are ex situ and in situ conservation. Article 2 of the Convention on Biological Diversity (CBD, 1992) provides the following definition of these categories:

**Ex situ** conservation means the conservation of components of biological diversity outside their natural habitats.

**In situ** conservation means the conservation of ecosystems and natural habitats and the maintenance and recovery of viable populations of species in their natural surroundings and, in the case of domesticates or cultivated species, in the surroundings where they have developed their distinctive properties.

There is an obvious fundamental difference between these two strategies: **ex situ** conservation involves the sampling, transfer, and storage of target taxa from the target area, whereas **in situ** conservation involves the designation, management, and monitoring of target taxa where they are encountered. Because of this fundamental difference, there is little overlap between the two strategies. The two basic conservation strategies may be further subdivided into the following specific techniques, which are discussed in Sections V.G and V.H:

**Ex Situ**
- Seed/embryo storage
- In vitro storage
- Semen/ovule/pollen/DNA storage
- Field gene bank/livestock parks
- Botanic/zoological garden

**In Situ**
- Genetic reserve
- On-farm

G. Ex Situ Techniques

In ex situ conservation, genetic variation is maintained away from its original location and samples of a species, subspecies, or variety are taken and conserved either as living collections of plants or animals in field gene banks, botanic or zoological gardens, and arboreta, or as samples of seed, semen, ovules, tubers, tissue explants, pollen, or DNA maintained under special artificial conditions.

1. Seed/Embryo Storage Conservation

**Ex situ** seed/embryo collection and storage is the most convenient and widely used method of genetic conservation (Fig. 3). Seeds and embryos are the natural dispersal, storage, or generative organs for the majority of species. This technique involves collecting samples from individuals or populations and then transferring them to a gene bank for storage, usually at sub-zero temperatures. The procedure used for the bulk of orthodox-seeded plant species is to dry the seeds or embryos to a suitable moisture content (5–6%) before freezing at −20°C, but this method is only suitable for species that can be dried and stored at low temperature without losing viability. The advantages of this technique are that it is efficient and reproducible, and feasible for short-, medium-, and long-term secure storage. However, the disadvantages are that there are problems in storing recalcitrant-seeded plant species. The latter species cannot be dried and frozen in the way used for orthodox seeds, because they rarely produce seed or are normally clonally propagated.

![Figure 3](image-url) Collecting seed from Tajikistan for ex situ conservation.
2. Botanical/Zoological Garden Conservation

Historically, botanical or zoological gardens were often associated with physic or medicinal gardens or displays of single specimens of zoological curiosities, and as such they did not attempt to reflect the genetic diversity of the species. These gardens now hold living collections of species that were collected in a particular location and moved to the garden to be conserved. The advantage of this method is that gardens do not have the same constraints as many other conservation agencies; they have the freedom to focus on wild species that may otherwise not be given sufficient priority for conservation. Yet there are two disadvantages to this technique. The first is that the number of species that can be genetically conserved in a botanical or zoological garden will always be limited because of the available space. The majority of these gardens are located in urban areas in temperate countries, and at their present sites most expansion would be prohibitively expensive. The majority of botanical and animal diversity is located in tropical climates, yet because most botanical and zoological gardens are in temperate countries, the collections must be kept in expensive greenhouses or other facilities, which also limits the space available. The second disadvantage is related to the first, namely, very few individuals of each species can be held, and this severely restricts the range of genetic diversity found in the wild that is protected. However, if the target species is very near extinction and only one or two specimens remain extant, this objection of course does not hold.

3. In Vitro Conservation

In vitro conservation involves the maintenance of ex-plants in a sterile, pathogen-free environment, and it is widely used for vegetatively propagated and recalcitrant-seeded species. This method offers an alternative to field gene banks. It involves the establishment of tissue cultures of accessions on nutrient agar and their storage under controlled conditions of either slow or suspended growth. The main advantage is that it offers a solution to the long-term conservation problems of recalcitrant, sterile, or clonally propagated species. The main disadvantages are the risk of somaclonal variation, the need to develop individual maintenance protocols for the majority of species, and the relatively high-level technology and high cost required. The best answer for cheap, long-term in vitro conservation in the future may be cryopreservation (Hoyt, 1988), that is, the storage of frozen tissue cultures at very low temperatures, for example, in liquid nitrogen at −196°C. If this technique can be perfected to reduce the damage caused by freezing and thawing, it may be possible to preserve materials indefinitely.

4. Field Gene Bank/Livestock Park Conservation

The conservation of germplasm in field gene banks or livestock parks involves the collecting of plant or animal specimens from one location and the transfer and conservation at a second site. It has traditionally been the method for recalcitrant- (whose seeds cannot be dried and frozen without loss of viability) or sterile-seeded plant species or for those species for which it is preferable to store clonal material. Field gene banks are commonly used for species such as cocoa, rubber, coconut, mango, coffee, banana, cassava, sweet potato, and yam. Livestock parks or rare breed centers, as distinct from zoos, emphasize captive breeding programs and therefore genetic conservation. The advantages of field gene banks and livestock parks are that the species are easily accessible for utilization and evaluation can be undertaken while the material is being conserved. The disadvantages are that the material is restricted in terms of genetic diversity, is susceptible to pests, disease, and vandalism, and may require large areas of land.

5. Pollen/Semen/Ovule/DNA Conservation

The storage of pollen grains is possible under appropriate conditions that allow their subsequent use for crossing with living plant material. It may also be possible in the future to regenerate haploid plants routinely from pollen cultures, but no generalized protocols have been developed yet. The development of artificial insemination techniques in recent years has made semen and ovule storage routine, especially for domesticated animals. The storage of DNA under prescribed conditions can easily and inexpensively be achieved given the appropriate level of technology, but the regeneration of entire organisms from DNA cannot be envisaged at present, although single or small numbers of genes could subsequently be utilized. The advantage of pollen storage is that it is low cost and simple, but the disadvantage is that only paternal material would be conserved, and with DNA storage there are problems with subsequent gene isolation, cloning, and transfer.

H. In Situ Techniques

In situ techniques involve the maintenance of genetic variation at the location where it is encountered, either in the wild or in traditional farming systems. The majority of existing nature reserves and natural parks were
established to conserve animals or to protect aestheti-

cally beautiful landscapes, but even today few have

plant conservation as their primary goal, let alone the

genetic conservation of species (Hoyt, 1988).

1. Genetic Reserve Conservation

Conservation of wild species in a genetic reserve in-
volves the location, designation, management, and
monitoring of genetic diversity in a particular natural
location (Fig. 4). This technique is the most appropriate

for the bulk of wild species, because it can, when the
management regime is minimal, be relatively inexpen-
sive. Whether dealing with plants or animals, the objec-
tive is to contain the minimum number of individuals

that can maintain genetic diversity within the species.

If too few individuals are protected, genetic diversity
will decline over time, and if too many are protected,
resources may be wasted in managing the large popula-
tion. To guide such efforts, conservationists will need
to estimate the effective population size (\(N_e\)), that is,

the number of conserved individuals that would un-
dergo the same amount of random genetic drift as the

actual population. Genetic reserves are appropriate for
animals as well as for orthodox and non-orthodox
seeded plant species, because numerous taxa can be
protected in a single reserve that allows the continued
evolution of species. However, the disadvantages are

that the conserved material is not immediately available
for human exploitation and, if the management regime
is minimal, little characterization or evaluation data
may be available. In the latter case, the reserve manager
may even be unaware of the complete specific composi-
tion of the reserve that he or she is managing.

2. On-Farm Conservation

Farmer-based conservation involves the maintenance
of traditional crop or animal breeds or cultivation sys-
tems by farmers within traditional agricultural systems.
On traditional farms, what are generally known as
‘land-races’ of plants are sown and harvested, and each
season the farmers keep a proportion of harvested seed
for re-sowing. Traditional breeds of domestic animal
are maintained by inter-breeding within and between
local village stocks. Thus the land-race or breed is highly
adapted to the local environment and is likely to contain
locally adapted alleles that may prove useful for specific
breeding programs. Home garden plant conservation is
a closely related variant of on-farm conservation of land-
races but on a smaller scale. It involves the cultivation
of more species-diverse material in home, kitchen,
backyard, or door-yard gardens. These home gardens
focus on medicinal, flavoring, and vegetable species
(e.g., tomatoes, peppers, digitalis, mint, thyme, pars-
ley). The overall advantage of the on-farm technique is
that it ensures the maintenance of highly adapted land-
races and breeds and those wild species that traditional
agriculture often depends on. However, these land-
races or traditional breeds may yield less than their
modern counterparts, and so traditional farmers may
require some subsidy and possibly monitoring to ensure
continued farming. It should be noted that contempo-
rary economic forces tend to act against the continued
farming of ancient land-races and breeds, which are
currently suffering rapid genetic erosion; many face
imminent extinction. A back-up system of ex situ con-
servation is therefore essential, as discussed in Sec-
tion VI.

I. Community-Based Conservation

When applying all of the conservation techniques dis-
cussed here, professional conservationists have often
failed to appreciate the role that local communities have
successfully played in conserving animal and plant di-
versity within their local environment. It is now gener-
ally accepted that the present-day wealth of domesti-
cated and non-domesticated biodiversity would not
exist were it not for the conscious effort of local commu-
nities over millennia to conserve biodiversity in all its
forms. For example, indigenous farmers in the Andes
maintain a gene pool of over 3000 varieties of potatoes
representing eight cultivated species, and in Papua New
Guinea approximately 5000 varieties of sweet potato
are cultivated, with a single farmer growing up to 20
varieties in one garden (McNeely et al., 1995). For wild
species, Prance et al. (1995) showed that four groups

FIGURE 4 Surveying plant populations for an in situ reserve in Turkey.
of Amazonian Indians use up to 79% of the tree species in their home ranges, and Milliken et al. (1992) in a similar study found that 81% of tree and vine species were utilized; this number rises to 86% when other categories of plants are added from literature sources. So local communities have had and continue to have an essential role in biodiversity conservation. They not only continue to conserve by using traditional practices for their own future direct and indirect benefit, but also increasingly work in collaboration with professional conservationists to conserve broad-based biodiversity for the benefit of their host countries and humankind as a whole. Specifically, collaboration involving conservationists and local communities increases the overall efficiency of "professional" conservation, because local communities have a broader local knowledge base concerning the animal and plant species found in their area. Local communities are therefore able to assist in the development of a more practical, focused, and hopefully efficient approach to locally targeted conservation. The employment of a collaborative approach also empowers local people and engenders increased pride in native biodiversity and its conservation. In this way, rather than deferring responsibility to outside science-based experts, they can retain environmental responsibility and take greater pride in maintaining their own environment.

J. Conservation Products

The products of conservation activities are primarily conserved germplasm (seed, embryos, semen, and ovules), live plants and animals, dried plants, cultures, and conservation data. Ex situ conserved orthodox seed or animal semen and ovules are commonly held in gene or semen banks at sub-zero temperatures and, for seed, low moisture content to prolong their life. Live plants or animals are conserved in genetic reserves, field gene banks, botanical or zoological gardens, or parks and research laboratories. Germplasm that is stored in a suspended form, such as tissue, pollen, or DNA, is kept as cultures in specialist laboratory facilities. Dried voucher plant specimens are held in herbaria and linked to specific samples of germplasm, and are as much as possible made representative of the conserved populations. Conserved material is ideally associated with a range of passport data, which detail the taxonomic, geographical, and ecological provenance of the material. All passport data should be entered into a database and made available for the management of the material, the formulation of future conservation priorities and strategies, and any exploitation. The various conservation products, where they are stored, and where they should be duplicated are presented in Table II.

K. Conserved Product Dissemination

The conservation products are either maintained in their original environment or deposited in a range of ex situ storage facilities. Whether the germplasm, voucher specimens, or passport data are conserved in situ or ex situ, to ensure its safety it should ideally be duplicated in more than one location. The distribution of duplicate

sets of material avoids accidental loss of the material due to fire, economic or political difficulties, warfare, or other unforeseen circumstances. Duplication of the data is relatively easy from the conservation database, and copies should be held by the commissioning agency, relevant host country institutes, and other interested parties.

L. Biodiversity Utilization

As discussed earlier, there should be an intimate linkage between conservation and utilization. The products of conservation, whether they be “living” or “suspended,” should be made available for use by humankind. Conservation can be seen as the safe keeping of preserved material, so that the material is available at a future date. In certain cases the material can be used directly, say in the selection of forage accessions or local domesticated animal breeds, where little breeding is undertaken. The conserved material may also be used in reintroduction programs where the traditional breed or land-race has been lost locally owing to civil unrest or the application of perverse government incentives that encourage the alteration of traditional practices.

More commonly, the first stage of utilization will involve the recording of genetically controlled characteristics (characterization) and the plant material may be grown out under diverse environmental conditions to evaluate and screen for drought or salt tolerance, or be deliberately infected with diseases or pests to screen for particular biotic resistance (evaluation). The biotechnologist will be screening for single genes, which when located may be transferred into a host organism to generate more rapid growth, for example. The biochemist (bioprospector) will be screening for particular chemical products that may be of use to the pharmaceutical industry. The products of utilization are therefore numerous, including new varieties, new crops, improved breeds, and pharmaceuticals as well as more nebulous but equally valuable products such as a beautiful or more diverse environment for human recreational activities.

VI. SUSTAINABLE AND INTEGRATED BIODIVERSITY CONSERVATION

Having discussed in detail what constitutes biodiversity and how that biodiversity can be conserved, the point should be made that any biodiversity conservation program should be sustainable and integrated. Each conservation technique has its advantages and disadvantages. The two strategies of ex situ and in situ conservation should not be seen as alternatives or in opposition to one another, but rather as being complementary, as stated in Article 9 of the Convention on Biological Diversity (CBD, 1992). One conservation strategy or technique can act as a backup to another, the degree of emphasis placed on each depending on the conservation aims; the type of species being conserved; the resources available, and whether the species has utilization potential. The efficacy of adopting an integrated approach to conservation, or as some have called it a “holistic” approach (Withers, 1993), is now well established as the only sustainable option. Therefore, when formulating an overall conservation strategy for a species, conservationists should think in terms of applying a combination of the different techniques available, including both in situ as well as ex situ techniques, where the different methodologies complement each other. It may be helpful to think of the various techniques as pieces in a jigsaw puzzle that will complete the overall conservation strategy and thus ensure the maintenance of plant or animal genetic diversity.

The adoption of an integrated approach requires the conservationist to consider the characteristics and needs of the particular gene pool being conserved, and then to assess which of the strategies or combination of techniques offers the most appropriate option to maintain genetic diversity within that taxon. To formulate the conservation strategy, the conservationist may also need to address not only biological questions but also the practical and political ones: What are the species’ storage characteristics? What do we know about its breeding success in captivity? Do we want to store the germplasm over the short, medium, or long term? How important is the species? Where is the species located and how accessible is it/does it need to be? Are there legal issues relating to access? How good is the infrastructure of the established reserves? What backup is necessary and/or desirable? How does the species conservation strategy fit within the local community development program? Given answers to these questions, the appropriate combination of techniques to conserve the gene pool can be applied in a pragmatic and balanced manner. The integration of conservation and community development is an important point to stress. We cannot expect local communities to altruistically forgo development for the benefit of a more abstract greater good, and so the practical application of the conservation strategy may need to be a compromise between scientific protocols and meeting the needs and
desires of local people. Therefore the actual combination of techniques will be formulated afresh for each species or group of species, demonstrating the flexibility of the integrated approach.

Sustainability in the sense of conformance is a fundamental concept for conservation. Whether seed, semen, or embryos are collected for ex situ conservation in a gene bank, animals are incorporated into a captive breeding program, or a habitat is designated as a reserve, each option has a financial cost and it would be a waste of limited conservation funds not to ensure that the conservation project is sustainable at least in the medium term. If the species or genetic material is lost from a reserve, the resources expended on establishing the reserve would have been wasted and the cost of rehabilitating populations using materials stored ex situ would have to be considered. The latter option is commonly expensive and may require extensive research to ensure that the reintroduced animals or plants do not likewise go extinct. Unfortunately, many conservation projects are funded on a short-term basis, so it is essential that an effective project exit strategy is developed so the conservation program itself is sustainable.

Not only is it necessary to integrate the different conservation strategies and techniques, and to involve the local community in a sustainable conservation project, but it is also important to integrate the different potential agencies involved. This is particularly true for large in situ reserve projects where the project may naturally span national borders and professional disciplines. In these cases, the project team must ensure that the local, provincial, national, regional, and international conservation agencies, as well as professionals from the different disciplines involved such as environmentalists, foresters, agriculturalists, and politicians, work together to promote the success of the conservation project.

GLOSSARY

air pollution Lowering of air quality due to release of toxic materials by factories, automobiles, fires, and other human activities.
disease Infections by parasitic organisms that can cause weakness, decreased reproduction, and death.
exotic species Species that occurs outside of its natural range owing directly or indirectly to human activity.
global climate change Current and predicted changes in global temperature, rainfall, and other aspects of weather due to increased human production of carbon dioxide and other greenhouse gases.
habitat fragmentation Process by which a continuous area of habitat is divided into two or more fragments by roads, farms, fences, logging, and other human activities.

overexploitation Harvesting of a natural resource, such as fish or timber, at a rate more rapidly than it can be naturally replenished.
water pollution Lowering of water quality due to input of sewage, pesticides, agricultural run-off, and industrial wastes that can result in harm to aquatic plants and animals.

IF SPECIES AND NATURAL COMMUNITIES ARE ADAPTED TO LOCAL ENVIRONMENTAL CONDITIONS, why should they be faced with extinction? Shouldn’t species and communities be able to persist in the same places that they have for thousands of years? Why are species going extinct now? The answers to these questions have become clear in recent decades: massive disturbances caused by people have altered, degraded, and destroyed the natural landscape on a vast scale, driving species and even communities to the point of extinction. Current rates of human-induced species extinctions are around 1000 times greater than past natural rates of extinction. The balance between natural rates of speciation and extinction have been drastically upset by human activities. The process of evolution will eventually create new species, but it will take thousands, if not millions, of years for these species to develop. And numerous unique species, such as pandas, elephants, and cheetahs, will be gone forever.
I. AN EXPANDING HUMAN POPULATION

The major threats to biological diversity that result from human activity are habitat destruction, habitat fragmentation, habitat degradation (including air and water pollution), the overexploitation of species for human use, the introduction of exotic species, and the increased spread of disease (Table I). Most threatened species face at least two or more of these threats, speeding their way toward extinction and hindering efforts to protect them. Typically, these threats develop so rapidly and on such a large scale that species are not able to adapt genetically to the changes or to disperse to a more hospitable location. These threats will continue to increase in the coming decades as the human population increases, as development and overexploitation continue, as the remaining natural habitats disappear, and as the global climate continues to change.

These threats to biological diversity are all caused by an ever-increasing use of the world’s natural resources by an expanding human population. In Europe, only 15% of the land area remains unmodified by human activities, and the amount of many specific habitat types remaining is below 10%. The greatest destruction of biological communities has occurred during the last 150 years, during which the human population grew from 1 billion in 1850, to 2 billion in 1930, to 6 billion in 1999. World population will reach an estimated 10 billion by the year 2050 (Fig. 1). Human numbers have increased because birth rates have remained high while mortality rates have declined, particularly during the last century, as a result of both modern medical discoveries (specifically the control of disease) and the presence of more reliable food supplies. Population growth has slowed in the industrialized countries of the world, but it is still high in many areas of tropical Africa, Latin America, and Asia, where the greatest biological diversity is also found.

People use natural resources, such as fuelwood, wild meat, and wild plants, and convert vast amounts of natural habitat for agricultural and residential purposes. Because some degree of resource use is inevitable, population growth is partially responsible for the loss of biological diversity. All else being equal, more people equals less biodiversity. Some scientists have argued strongly that controlling the size of the human population is the key to protecting biological diversity. However, population growth is not the only cause of species extinction and habitat destruction: overconsumption of resources is also responsible. The rise of industrial capitalism and materialistic modern societies has greatly accelerated demands for natural resources, par-

* From Reid and Miller (1989), based on data from various sources.
* These values represent the percentage of species that are influenced by the given factor. Some species may be influenced by more than one factor, thus the rows may exceed 100%.
* Overexploitation includes commercial, sport, and subsistence hunting, as well as live animal capture for any purpose.
* Threatened species and subspecies include those given in the IUCN categories critically endangered, endangered, and vulnerable.
Extinction, Causes of

A. Unequal Use of Natural Resources

In many countries there is extreme inequality in the distribution of wealth, with a small percentage of the population controlling, owning, and consuming much of the wealth and natural resources such as good farmland, livestock, and timber resources. As a result, poor, rural people with no land or resources of their own are forced by necessity to destroy biological communities and hunt endangered species to extinction. Large landowners and business interests that force local farmers off their land is a common pattern in many countries of the developing world, a pattern often backed up by the government, the police, and the army. Political instability, lawlessness, and war also displace farmers into remote, undeveloped areas where they feel safer; most practice shifting cultivation, a form of agriculture involving cutting down forest, burning the plant material, and planting crops in the nutrient-rich ash, because it is the simplest way to make a living when they may be obliged to move again within a short time. The landless farmers and their families often exploit natural resources in their surroundings just to stay alive; often these resources are components of species-rich biological communities.

The responsibility for the destruction of biological diversity in species-rich tropical areas also lies in the unequal use of natural resources worldwide (Fig. 2). People in industrialized countries (and the wealthy minority in the developing countries) consume a disproportionate share of the world's energy, minerals, wood products, and food. Each year the average U.S. citizen uses 43 times more petroleum products, 34 times more aluminum, and 386 times more paper products than the average citizen of India. Wealthy countries and individuals leave a widespread "environmental footprint" in which their excessive patterns of consumption affect a wide area of the world that must supply their needs. This excessive consumption of resources is not sustainable in the long run. If this pattern is adopted by the expanding middle class in the developing world, it will cause massive environmental disruption.

B. Large-Scale Development Projects

In many cases, the factors causing habitat destruction, particularly in the developing world, are the large industrial and commercial activities associated with a global economy—such as mining, cattle ranching, commercial fishing, forestry, plantation agriculture, manufacturing, and dam construction—and initiated with the goal of making a profit. Many of these projects are funded by
national governments and international development banks and are touted as sources of jobs, commodities, and tax revenues. Others are initiated and funded by large multinational corporations. However, this exploitation of natural resources often is neither efficient nor cost-effective because the emphasis in these industries is on short-term gain, often at the expense of the long-term sustainability of the natural resources, and generally with little regard for the local people who depend on the resources.

II. HABITAT DESTRUCTION

Increasing human populations and their activities use even greater proportions of the world’s terrestrial and marine environments and associated natural resources, resulting in the inevitable destruction of species, genetic variation, habitats, and ecosystem processes.

A. Habitat Loss
